In **rectovaginal fistulae**, the tall, columnar, **mucus-producing colonic epithelial cells** may be recognized in cervicovaginal smears because of their large size and columnar configuration. These cells usually occur in compact sheets or clusters with basal nuclei and smooth luminal epithelial surface. The differential diagnosis is with vaginal adenosis (see below) and with endocervical or endometrial benign or malignant cells, which are usually smaller. The endocervical-type cells that have sometimes been observed in vaginal smears in **posthysterectomy patients** may also be confused with colonic cells. The colonic cells are often accompanied by bowel contents in the form of fecal material, often containing indigested **muscle or vegetable fibers and plant cells** originating in the colon (see Chap. 8). Because the nuclei of the plant cells are large and dark they may be mistaken for cancer cells. For further discussion of plant cells and their identification in sputum, see Chapter 19.

In **vesicovaginal fistulae**, the multinucleated, **large urothelial umbrella cells**, derived from the epithelium of the bladder, can **sometimes be identified in cervicovaginal smears**. These cells can be mistaken for cancer cells (see Chap. 22 for a detailed description of these cells).

Foreign Bodies

A variety of foreign material and foreign bodies, described in Chapter 8, may be found in the vagina and, hence, in cervicovaginal smears.

Benign Tumors and Tumorous Conditions

Except for **condylomata acuminata** and **vaginal adenosis** (to be discussed below), benign tumors and tumorous conditions are infrequent in the vagina and of very limited significance in diagnostic cytology. **Endometriosis, cysts or benign tumors of Gartner ducts**, and very uncommon benign tumors, **such as leiomyomas or rhabdomyomas**, occur in the wall of the vagina, do not produce any perceptible abnormalities in the vaginal epithelium and, hence, cannot be recognized cytologically, except by aspiration biopsy.

Vaginal and Cervical Adenosis

Natural History

A synthetic compound with estrogen-like effect, **diethylstilbesterol (DES)**, was extensively used for prevention of abortions and other complications of pregnancy during the late 1940s and early 1950s. About 20 years later, it became apparent that the use of this drug adversely affected the offspring of the patients so treated.

In some of the **male offspring**, cysts of the epididymis and abnormal spermatogenesis were observed, a finding of limited cytologic significance (Gill et al, 1976). In the **female offspring**, **vaginal and cervical adenosis** has been observed, a disorder caused by **a replacement of vaginal squamous epithelium by glandular epithelium**, that on inspection appear as **red patches in the upper reaches of the vagina and adjacent cervix**. In about 40% of the

affected females, there are also abnormalities in the gross configuration of the vagina and the cervix, described as **ridges**. **Most importantly, adenocarcinomas and squamous carcinomas and precursor lesions were observed in a small subset of females with vaginal adenosis.** These lesions are discussed below.

It has been shown by Sonek et al (1976) that DES administered between the seventh and eighth weeks of pregnancy resulted in 100% of adenosis in the offspring; if the drug was administered later during pregnancy, the frequency of adenosis was reduced but remained at about 70%.

Although there has been considerable speculation as to the mechanism of formation of adenosis, the evidence currently available strongly suggests that DES inhibits the transformation of the müllerian cuboidal epithelium into squamous epithelium that normally takes place during the last stages of the fetal life. A similar mechanism, although on a very limited scale, must be evoked in reference to cervical eversion or ectropion (see Chapter 10). Thus, **adenosis may be conceived as a very large eversion of the endocervical epithelium**, affecting the outer portions of the uterine cervix and the adjacent vagina. This has been confirmed by ultrastructural studies (Fenoglio et al, 1976). Experimentally, adenosis can be induced in mice by estrogen treatment (Forsberg, 1976). Vaginal adenosis was also reproduced in the female offspring of the monkey, *Cebus apella*, exposed to DES during pregnancy (Johnson et al, 1981).

It is of interest, though, that exposure to **DES is not a mandatory event in vaginal adenosis**. Robboy et al (1986) reported 41 patients with this disorder who had no DES exposure. Adenosis of the vagina has also been observed **after treatment with 5-fluorouracil and carbon dioxide laser**, usually for extensive condylomas of the vulva and vagina (Sedlacek et al, 1990; Goodman et al, 1991; Bernstein et al, 1983). A case of vaginal adenosis in a patient on **Tamoxifen therapy** was reported by Ganesan et al (1999).

Histology

In adenosis, areas of **proximal vagina and adjacent outer rim of the uterine cervix are lined by mucus-producing glandular epithelium, usually of the endocervical type**, replacing the normal squamous epithelium. Occasionally, the epithelium resembles that of the **endometrium or the fallopian tubes**. The glandular epithelium also forms tubular glands of endocervical type in the lamina propria that may reach the muscularis (Fig. 14-1A,B).

All changes commonly observed in the endocervical epithelium may be observed in adenosis: **tubal metaplasia, squamous metaplasia, and malignant transformation leading to adenocarcinoma, epidermoid carcinoma and its precursor lesions, or both.**

With the discontinuation of the use of DES for prevention of obstetrical difficulties, adenosis has become a rare disorder, limited to those few women, daughters of DES-exposed mothers, now in their 50s or 60s, and the rare

P.468

women who develop it spontaneously or after treatment (see above). Nonetheless, for the sake of completeness, we have retained the description of the cytologic manifestations of this disorder.

Figure 14-1 Vaginal adenosis. A. Endocervical type epithelium lining the surface of the vagina. B. Residual endocervical type glands underneath the squamous epithelium lining the vagina. C. Vaginal scrape smear containing scattered endocervical type cells next to squamous cells. D. Scrape of adenosis. The dominant cells are parabasal cells from squamous metaplasia.

Cytology

The purpose of cytologic examination of the vagina in children and women at risk is to determine the **presence of adenosis and of malignant changes, if any, by non-invasive methods**. Unfortunately, in uncomplicated adenosis, the cytologic techniques are not very efficient because the glandular epithelium does not desquamate easily. The best method is based on **direct scrapes of the lesions under visual control**; this approach is applicable only to adult women. In children and vaginal adolescents, a **vaginal pool smear** obtained by a small pipette is the only method available.

Vaginal Pool Smears

Adenosis is characterized by **mucus-secreting columnar endocervical cells** of various sizes, occurring singly or in clusters, **or endocervical cells showing transition to squamous metaplasia** (Fig. 14-1C,D). The diagnosis is possible because the finding of normal endocervical cells in vaginal smears is otherwise exceptional. The finding of small squamous cells ("metaplastic cells"), unless in company of columnar mucus-secreting cells, is of a very limited diagnostic value because such cells may also originate in normal squamous epithelium. The efficacy of diagnosis of adenosis in vaginal pool smears is low.

Direct Scrape Smears From Areas of Adenosis

This is the sampling method of choice in adult women at risk. Bibbo et al (1975) advocated

taking **four separate scrape smears from the four quadrants of the proximal vagina**. This may be supplemented by direct smears of the outer portio of the uterine cervix, preferably under visual control. **Prior to cytologic sampling, the accumulated mucus should be removed with a gauze sponge.**

Direct vaginal scrape smears from cases of adenosis contain

P.469

either **secure or presumptive evidence of disease**. Secure evidence of disease is either the presence of glandular cells of endocervical type or glandular cells showing transition to squamous metaplasia. The presence of small squamous cells, singly or in clusters ("metaplastic cells"), cannot be considered as secure evidence of adenosis. Other cell types listed by Bibbo et al (1975), such as anucleated squamous cells or dyskaryotic squamous cells (dysplastic cells), have no specificity whatsoever for adenosis. Applying these criteria to Bibbo's series of 66 patients with known adenosis, the cytologic diagnosis of this disorder could be securely established in nine patients and a presumptive diagnosis of adenosis based on "metaplastic cells" in an additional 33 patients. The **limited value of cytology in the diagnosis of uncomplicated adenosis** was also emphasized by Robboy et al (1986), who could establish the diagnosis of adenosis in only 22% of 575 such patients.

Confirmation of the Cytologic Diagnosis of Adenosis

This is best accomplished by colposcopy. The colposcopist can clearly identify the extent of adenosis and, more important perhaps, examine the large and sometimes multiple transformation zones for evidence of possible neoplastic lesions. If colposcopy is not available, Schiller's test will disclose iodine-negative areas of glandular mucosa within the vagina and the outer cervix.

Clinical Significance

Melnick et al (1987) estimated the **risk of adenocarcinoma at 1 case per 1,000 women** with adenosis through the age of 34 years. The peak incidence was at 19 years of age but tumors have been observed in children as young as 7 and in women age 30 (Herbst and Bern, 1981). Tuboendometrial type of epithelium appears to be the most common source of adenocarcinomas (Robboy et al, 1982, 1984). By far more common in adenosis are the **precursor lesions of squamous cancer in the vagina and the adjacent cervix** (see below).

Follow-up of many thousands of patients with adenosis disclosed the very high probability of **self healing. The glandular epithelium undergoes squamous metaplasia which becomes mature** and identical to normal squamous epithelium. Thus, unless there is evidence or suspicion of malignant transformation, it appears safe to observe these patients without treatment. Adenocarcinomas and premalignant or malignant squamous lesions observed in patients with adenosis are discussed below.

Malignant Tumors

The most common primary malignant tumors of the vagina are **carcinomas of squamous derivation and type**. Since the appearance of adenosis on a large scale, increased attention has been devoted to **adenocarcinomas** associated with this disorder. Primary adenocarcinomas, in the absence of adenosis, are very uncommon, although they have been repeatedly observed. **Rare tumors**, including **malignant melanomas, sarcomas**, and

metastatic tumors to the vagina are discussed in Chapter 17. **Postradiation carcinoma in situ** (dysplasia) of the vagina is discussed in Chapter 18.

Squamous Carcinoma

Invasive squamous carcinomas of the vagina and their precursor lesions are usually observed in women past the age of 40. In approximately 50% of these patients, there is evidence of a **synchronous or metachronous squamous carcinoma of the uterine cervix** that may be invasive or in situ (Kanbour et al, 1974; Murad et al, 1975; Lee and Symmonds, 1976). Bell et al (1984) also observed vaginal cancer in several patients after hysterectomy for allegedly benign disease. Norris et al (1970) reported a case of vaginal squamous carcinoma in an infant.

Association of vaginal carcinomas with other malignant tumors of the female genital tract may also occur. We have personally observed synchronous or metachronous tumors of the vagina, vulva, and occasionally of the endometrium, tube, and ovary. Thus, the presence of a vaginal carcinoma should automatically trigger the search for other malignant lesions. Conversely, **follow-up of patients with carcinoma or precancerous states of the epithelium of the uterine cervix and the vulva must include periodic examinations of the vagina.**

Observations pertaining to the possible role of **human papillomavirus (HPV)** in the genesis of cervical carcinoma are also applicable to squamous carcinomas of the vagina and vulva (see Chap. 11). The proof of viral presence in the relatively uncommon vaginal lesions is not nearly as extensive as for the cervical and vulvar squamous carcinomas and their precursor lesions. Still, there is no doubt that the vaginal neoplastic disorders follow the pattern of cervical disease and share identical cytologic, histologic, and biologic backgrounds (Okagaki et al, 1984).

Histology

Most squamous carcinomas of the vagina are keratin-producing, both on the surface of the epithelium of origin and within the invasive and metastatic foci. Occasionally, such lesions have thick layers of keratin on their surfaces and may bear considerable similarity to the warty (verrucous) carcinomas of various organs (Fig. 14-2). The tendency to keratin formation is also observed in precancerous lesions (see below). **Nonkeratinizing (epidermoid) carcinomas of the vagina made up of medium-size cells or small cells may also occur** (Fig. 14-3). Small cell carcinomas with endocrine features were described by Albores-Saavedra et al (1972) and by Chafe (1989). In a case reported by Colleran et al (1997), the tumor was shown to be secreting ACTH and causing a Cushing's syndrome.

The term **microinvasive carcinoma of the vagina** was discussed by Peters et al (1985), based on experience with six patients with invasion up to 2.5 mm in whom the results of surgical treatment by partial or total vaginectomy were uniformly good. **In our experience, however, even superficially invasive vaginal carcinomas are capable of forming metastases. Two territories of lymph nodes may be involved: carcinomas of the distal third of the vagina usually form metastases to the inguinal lymph nodes; carcinomas of the proximal third may metastasize to pelvic lymph nodes; carcinomas of the middle third may metastasize to either or both of these two groups of**

P.470

lymph nodes. The reasons for the very aggressive behavior of carcinomas of the vagina are

not clear. Presumably, the lack of a thick muscularis and the abundance of lymphatics in the vaginal wall account for the striking differences in behavior when compared with the superficially invasive carcinomas of the uterine cervix (see Chap. 11).

Figure 14-2 Keratinizing squamous carcinoma of the vagina. A. Keratinized carcinoma in situ from which well-differentiated squamous carcinoma shown in B was derived. C,D. Various aspects of small squamous cancer cells in a vaginal smear.

We have also observed a case of a bulky **vaginal tumor with features of pseudosarcoma**. On the surface of the lesion, there was a squamous carcinoma in situ. The stroma of the tumor was composed of spindly cells mimicking a sarcoma with focal differentiation into an invasive squamous carcinoma (Fig. 14-4). This tumor was identical to the uncommon tumors of this type observed in the esophagus and adjacent organs described in Chapter 25.

Squamous Carcinoma In Situ and Related Lesions (Vaginal Intraepithelial Neoplasia; VAIN)

Carcinomas in situ and noninvasive epithelial lesions with lesser degrees of abnormality (“dysplasias”) have been grouped as **vaginal intraepithelial neoplasia (VAIN)** that can be graded I, II, III as initially proposed for similar lesions of the uterine cervix (see Chap. 11). Although the Bethesda nomenclature (see Chap. 11) has not been extended to the vagina, it appears reasonable to classify **VAIN I as low-grade lesions** (mild dysplasia with features of condyloma) (Fig. 14-5) and **VAIN II and III as high-grade lesions**. This suggestion gained support from a study by Sherman and Paull (1993) who documented better reproducibility of diagnoses, using the binary system. Logani et al (2003) reported that most of the precancerous lesions of the vagina contain high risk HPV, contrary to vulvar lesions. These authors also noted that staining with proliferation antigen M1B1 helps in distinguishing benign from potentially malignant epithelial changes.

The **clinical appearance** of these lesions depends on the level of keratinization: **the heavily keratinized lesions appear as white patches (leukoplakia)**, whereas the **poorly differentiated (epidermoid) lesions with limited keratin formation may appear as red**

areas in the vagina (Hummer et al, 1970).

Predictably, **the low-grade lesions resemble structurally normal squamous epithelium**, except for the presence of nuclear enlargement, hyperchromasia, and mitotic activity (Fig. 14-5). In the presence of **koilocytes, the lesions are identical to the so-called flat condylomas observed on the surface of the uterine cervix** (see Chap. 11). Keratin deposits are often present on the surface. The **low-grade lesions** may occur as **multiple condylomas that form small elevations of the vaginal epithelium (condylomatous colpitis)** and are often associated with similar lesions on the vulva; although these lesions are difficult to eradicate, they are not considered threatening to the patient. They have been observed in children, presumably as a consequence of sexual abuse. More important is the **single low-grade**

P.471

lesion. Although many of these lesions may disappear, presumably spontaneously or after treatment, there is at least some evidence, based on personal experience, that the **vaginal low-grade lesion may progress to invasive cancer more rapidly and more frequently than similar lesions in the uterine cervix.** This observation has received support from a follow-up study of untreated VAIN by Aho et al (1991) who also observed the progression of a low grade lesion to invasive cancer.

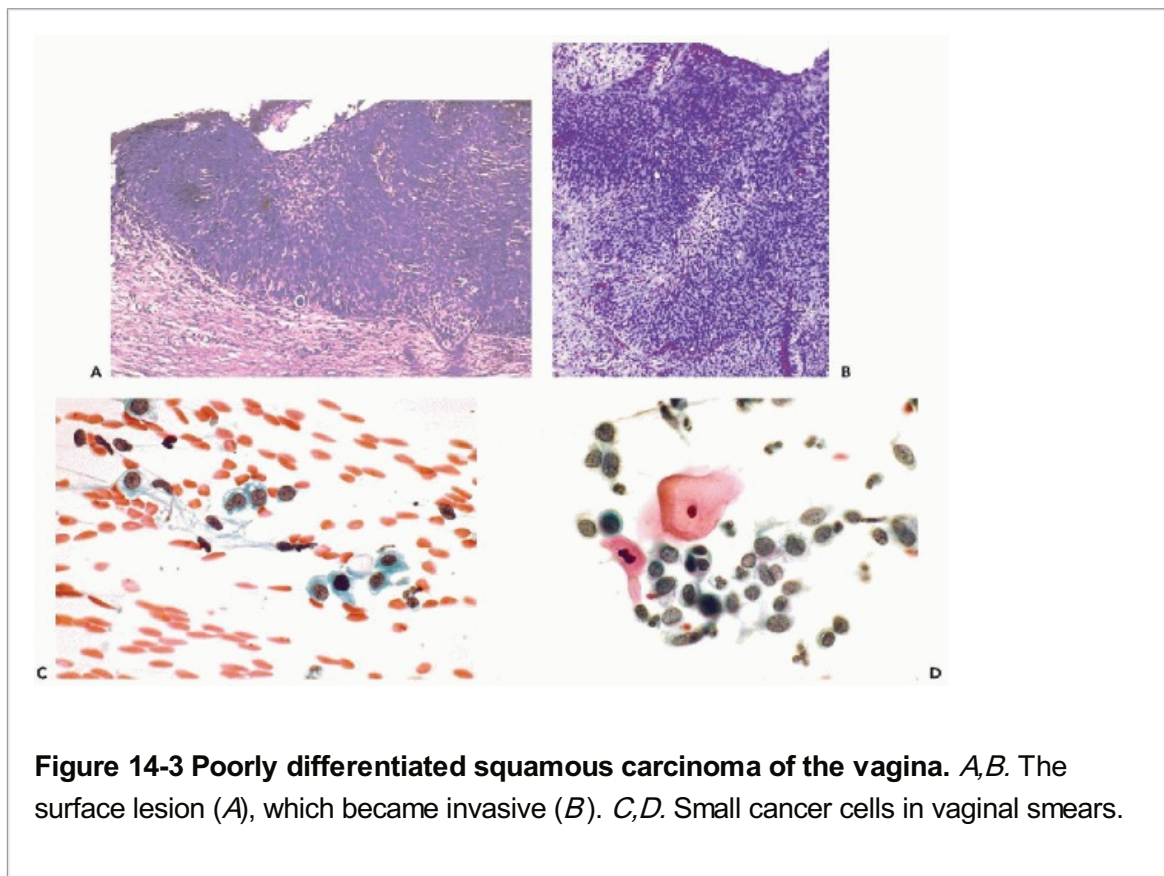

Figure 14-3 Poorly differentiated squamous carcinoma of the vagina. A,B. The surface lesion (A), which became invasive (B). C,D. Small cancer cells in vaginal smears.

The **high-grade lesions fall into two groups: keratin-forming lesions, that may show remarkable similarity to low-grade lesions** except for the presence of abnormal cells throughout the thickness of the epithelium (see Fig. 14-2A); and **nonkeratinizing lesions that are similar to high-grade lesions of the endocervical canal**, composed of smaller malignant cells and show little or no keratin formation on the surface (see Fig. 14-3A). Anecdotal evidence has been accumulated that these lesions, particularly the classical carcinoma in situ, have the ability to progress to invasive squamous cancer (Rutledge, 1967;

Benedet and Sanders, 1984; Aho et al, 1991), although the frequency of progression remains unknown because few of these lesions are followed without treatment.

Cytology

The customary source of diagnosis of vaginal carcinoma is the smear obtained by aspiration of the vaginal pool. Occasionally, however, cancer cells of vaginal origin may be observed in cervical smears.

If cervical and/or vaginal smears contain evidence of squamous carcinoma or a related precancerous lesion and there is no evidence of disease in the uterine cervix, the vagina must be investigated. Direct scrape smears of the vaginal wall may be used initially to confirm the diagnosis. On occasions when there is no visible mucosal abnormality, we have recommended **mapping smears**, i.e., taking multiple, separately labeled smears from separate vaginal sites to identify the source of the abnormal cells for biopsy.

Invasive Carcinoma

Invasive keratinizing epidermoid carcinomas of the vagina closely resemble invasive squamous carcinomas of the uterine cervix. Most tumors shed relatively **highly differentiated squamous cancer** cells of various sizes with thick, yellow or orange cytoplasm (see Fig. 14-2). Keratin "pearls" of malignant type and bizarre cell types (tadpole cells, spindly cells) are common. **Koilocytes** may be observed, suggesting

P.472

the origin of such lesions from "flat condylomas." Necrosis, which is so commonly present in invasive cancer of the cervix, is often absent. Inflammation and trichomoniasis are commonly observed.

Figure 14-4 Pseudosarcomatous squamous carcinoma of the vagina. The polypoid lesion with smooth surface was clinically protruding into vaginal lumen. *A.* Squamous carcinoma in situ on the surface of a tumor composed of spindly cells, shown in *B.* *C.* Focus of squamous differentiation in the invasive spindly component of the tumor. *D.* A vaginal pool smear from a similar case showing well-differentiated squamous cancer cells.

Invasive nonkeratinizing carcinomas are made up of smaller cancer cells with less evidence of keratin formation (see Fig. 14-3). Occasionally, only small, undifferentiated cancer cells are present. Other features of such smears are similar to those described above.

Cytologic findings in a case of **small-cell neuroendocrine carcinoma** of vagina were described by Ciesla et al (2001). Numerous small cancer cells, some with nuclear molding, were observed and illustrated.

Precursor Lesions of Vaginal Squamous Carcinoma (VAIN)

Low-Grade Lesions (VAIN Grade I, Mild Dysplasia, Flat Condylomas)

The cytologic presentation of these lesions, shown in Figure 14-5D, consists of **superficial and intermediate dyskaryotic (dysplastic) squamous cells and koilocytes**, characterized by a delicate, transparent cytoplasm and enlarged, irregular, hyperchromatic nuclei, often surrounded by a clear zone. The underlying tissue abnormality (Fig. 14-5B) is very similar to that of low-grade lesions occurring on the uterine cervix (see Chap. 11).

High-Grade Lesions (Carcinoma In Situ, VAIN Grade II or III)

Precursor lesions of epidermoid carcinoma often follow, or are synchronous with, similar lesions of the uterine cervix, most often the keratin-forming type. **Two types of high-grade lesions (carcinoma in situ) may be observed in the vagina.** The uncommon **small cell type** is characterized by the presence of small cancer cells, occurring singly or in clusters (see Fig. 14-3C,D). These lesions and their cytologic presentation usually follow and are akin to the “classic” small cell carcinoma in situ of the uterine cervix (see Chap. 11).

More common are the **keratin-forming** high grade lesions (keratinizing carcinomas in situ (Fig. 14-6). These lesions shed dyskaryotic (dysplastic) and **squamous cancer cells of variable sizes**, some with opaque, thick, keratinized cytoplasm and large pyknotic nuclei. **Koilocytes** with a wide perinuclear clear zone are commonly present. The tissue, however, may disclose a high-grade lesion capable of invasion, showing residual evidence of a condyloma (Fig. 14-6D). These lesions are **clear examples of malignant**

P.473

transformation of low-grade (condylomatous) lesions that may be particularly dangerous in the vagina. One should not be misled by the presence of koilocytes into believing that the lesion will disappear without treatment.

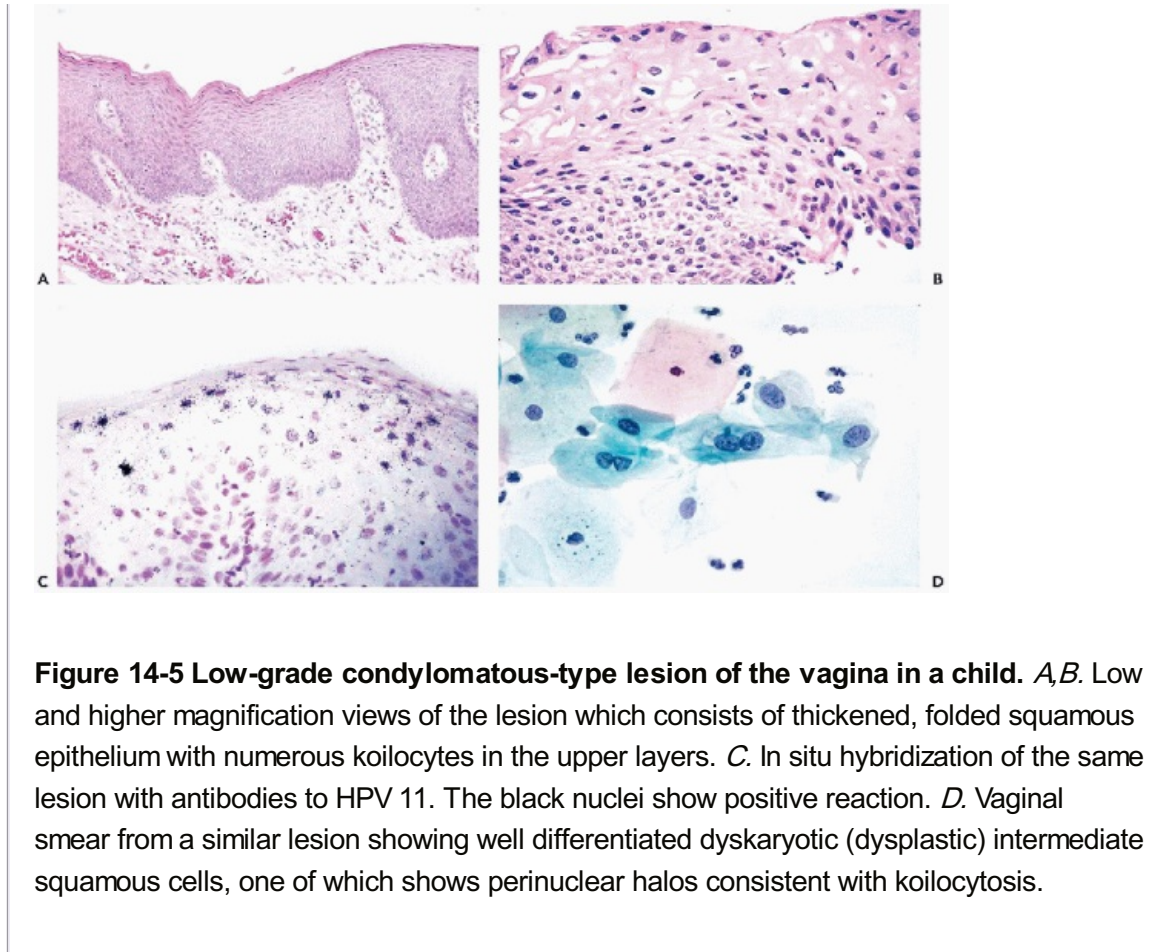

Figure 14-5 Low-grade condylomatous-type lesion of the vagina in a child. *A,B.* Low and higher magnification views of the lesion which consists of thickened, folded squamous epithelium with numerous koilocytes in the upper layers. *C.* In situ hybridization of the same lesion with antibodies to HPV 11. The black nuclei show positive reaction. *D.* Vaginal smear from a similar lesion showing well differentiated dyskaryotic (dysplastic) intermediate squamous cells, one of which shows perinuclear halos consistent with koilocytosis.

High-grade VAIN lesions are not infrequently observed in postmenopausal women with atrophic smear pattern. As was discussed in Chapter 11 in reference to similar lesions of the uterine cervix, the recognition of cancer cells in dry, atrophic smears may be fraught with difficulty, particularly because the feature of nuclear hyperchromasia is not readily evident in dry cancer cells spread on the slide. **In such smears, the *nuclear size* and the *nucleocytoplasmic ratio*** become the principal criteria of recognition of cancer cells: the nuclei are substantially larger than those of benign squamous cells in the same smears, and the nucleocytoplasmic ratio is altered in favor of the nucleus. Reviving the epithelium with estrogen may be quite helpful in the diagnosis.

It is quite evident that there are significant cytologic similarities between the low-grade lesion shown in Figure 14-5 and the high-grade keratin-forming lesion shown in Figure 14-6. The difference lies in the cytoplasm which, in many cells derived from the high-grade lesion, is heavily keratinized and opaque whereas it is more transparent and delicate in the low-grade lesion.

Cytologic assessment of the type of histologic abnormalities, which may be carried out with reasonable accuracy in the uterine cervix, is rarely possible with vaginal lesions. The **cytologic presentation of vaginal low-grade lesions, carcinoma in situ, and invasive carcinoma may overlap significantly.** The presence or the absence of necrosis is of limited diagnostic help.

Because of the potentially highly malignant behavior of these lesions, **any cytologic evidence of a neoplastic process in the vaginal epithelium, regardless of the degree of cytologic abnormality, must be followed by an attempt to localize and destroy the lesion** before metastases set in. Colposcopy, or, if unavailable, Schiller's test or mapping smears (see above),

will help in localizing the disease and in obtaining histologic evidence. If the lesion is still confined to the epithelium, surgical excision, carbon dioxide laser treatment, or chemotherapy with 5-fluorouracil ointment, may prove curative, although the treatment may lead to formation of vaginal adenosis (see above).

P.474

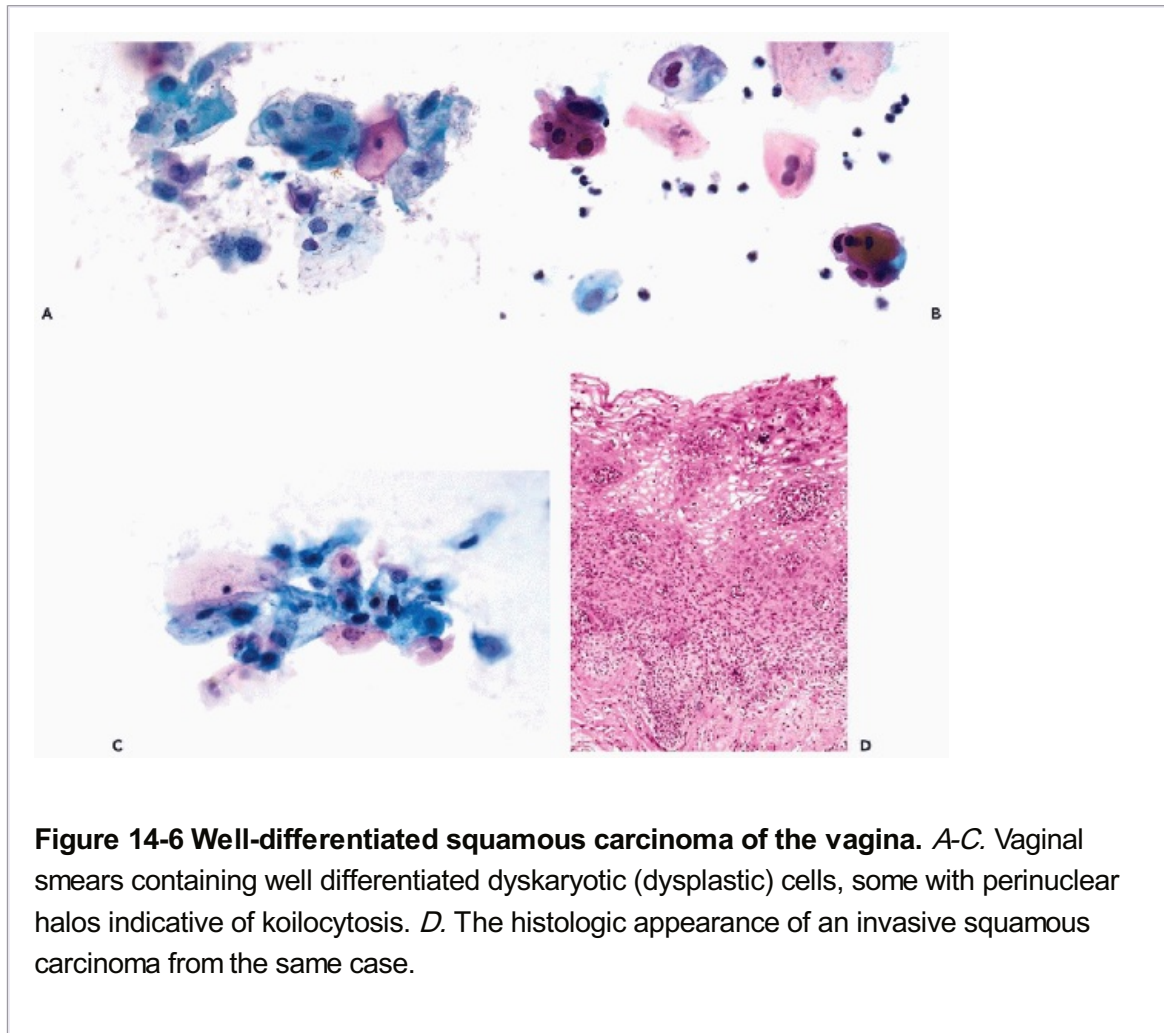

Figure 14-6 Well-differentiated squamous carcinoma of the vagina. A-C. Vaginal smears containing well differentiated dyskaryotic (dysplastic) cells, some with perinuclear halos indicative of koilocytosis. D. The histologic appearance of an invasive squamous carcinoma from the same case.

Vaginal Adenosis and Squamous Carcinoma and Its Precursors

In discussing the nature of adenosis (see above), it has been pointed out that the presence of endocervical tissue in the vagina greatly increased the size of the transformation zone. Because of the important role that the transformation zone plays in the genesis of epidermoid carcinoma of the uterine cervix (see Chap. 11), it has been anticipated by us in early editions of this book that squamous carcinoma and its precursors will be encountered with increasing frequency in adenosis. These observations were amply confirmed. Thus, Staff et al (1974), Bibbo et al (1975), and Fetherston (1975) observed several instances of dysplasia and epidermoid carcinoma in situ in the vagina adjacent to adenosis. The incidence of these lesions was estimated by Robboy et al (1984) at 15.7 per 1,000 person-years of follow-up, approximately double the rate of an unexposed population. Most of these lesions can be identified by cytologic sampling of the vagina and adjacent cervix (see Fig. 14-9). Two cases of invasive squamous carcinoma occurring in adenosis were reported by Veridiano et al (1976).

Adenocarcinoma of the Vagina

Adenocarcinomas of the vagina, otherwise very rare, assumed new importance in the generation of women afflicted with DES-induced vaginal adenosis (Barber and Sommers, 1974; Robboy et al, 1976). **Adenocarcinoma occurring in adenosis affected girls and very young women, often in their teens, many of whom are initially asymptomatic.** Cytologic examination may serve a dual purpose: as a means of detection of adenocarcinoma or as a follow-up procedure after treatment of the lesion.

Taft et al (1974) summarized their experience with 95 cases from the registry of these tumors maintained at the Massachusetts General Hospital in Boston, Massachusetts. In 11 asymptomatic patients, **the tumors were detected by cervicovaginal cytology.** The smears were positive or suspicious in 43 of 55 patients with prior positive biopsies.

P.475

In three patients, vaginal smears served as the first indication of local recurrence after treatment. Thus, cytologic evaluation plays an important role in the diagnosis and management of these patients.

Histology

Adenocarcinomas originating in adenosis are, in many ways, similar to endocervical adenocarcinomas and to adenocarcinomas of Gartner duct origin (see Chap. 12). The neoplastic glands are lined by cuboidal and sometimes columnar cells, often protruding into the lumen in hobnail fashion (Figs. 14-7D and 14-8D). Because the cytoplasm of many of these cells is transparent, the term **clear cell carcinoma or mesonephric carcinoma** is often used to describe these tumors. Occasionally, the tumors resemble the endometrial type of adenocarcinoma and are then associated with foci of adenosis resembling endometrial glands or endometriosis. In all tumors, foci of solid growth may be observed.

The origin of the tumors can be traced to the glandular surface epithelium; more often, however, the lesion originates from the deep glands. It is theoretically predictable that an adenocarcinoma in situ must exist in adenosis, but such a lesion has not yet been described.

nucleoli. In *B* and *C*, the cells are elongated and have a vague similarity to endocervical cancer cells. *D*. corresponding tissue lesion shows an invasive adenocarcinoma derived from adenosis. (Case courtesy of Dr. Priscilla Taft, Massachusetts General Hospital, Boston, MA.)

A very rare **adenocarcinoma of intestinal type** of the vagina, derived from an adenoma, was described by Mudhar et al (2001) who also reviewed the literature. We have not seen a tumor of this type.

Cytology

Adenocarcinoma originating in adenosis may involve the vagina and, in about 40% of the cases, the adjacent cervix. If the uterine cervix is involved, the cervical scrape smear is very efficient in the diagnosis of the tumor. If only the vagina is involved, the cervical smear will fail to reveal tumor in many cases. Thus, the **importance of a vaginal pool smear** in young women, particularly those at risk for adenosis and adenocarcinoma, cannot be sufficiently emphasized. Direct scrape smears of the vaginal wall in patients with high risk for adenosis have been discussed above. Such smears, although not particularly efficient in the diagnosis of benign adenosis, are very helpful in the diagnosis of vaginal adenocarcinoma.

In their classic form, the well-preserved cells of vaginal adenocarcinoma appear as **polygonal or columnar cancer cells singly and in clusters** (Fig. 14-7A,B). The cells vary in size and measure from 20 to 30 µm in their largest dimensions. The **cytoplasm is delicate, transparent, and**

P.476

generally basophilic, sometimes studded with small vacuoles. The large nuclei appear finely granular. The nucleoli vary in size and may be very large in some cancer cells. In most cases, however, when the tumor cells are less well preserved, the characteristic features described above may not be present. In such situations, clusters of **small cancer cells without distinguishing features** are commonly seen (Fig. 14-8A,B). Origin from an adenocarcinoma may be suspected if the cytoplasm is vacuolated and infiltrated with polymorphonuclear leukocytes or if the clusters have papillary configuration and the cells have large nucleoli. **In many instances, the identification of tumor type may not be possible on cytology alone.** Taft et al (1974) pointed out the similarity of this cytologic presentation with that of epidermoid carcinoma. **Very bizarre, large cancer cells** that may be occasionally observed (Fig. 14-7C) may suggest a sarcoma.

Figure 14-8 Adenocarcinoma of the vagina in a young woman. *A,B.* Relatively small cancer cells resembling a squamous rather than a glandular lesion. *C.* Focus of adenocarcinoma of the vagina adjacent to normal vaginal squamous epithelium. *D.* Details of the tumor composed of convoluted and papillary glands. Note the “hobnail” arrangement of tumor cells. (Case courtesy of Dr. Priscilla Taft, Massachusetts General Hospital, Boston, MA.)

The smears in vaginal adenocarcinoma contain a large admixture of squamous cells of vaginal origin that may partly obscure the evidence of cancer. Also if there is adjacent residual adenosis, in the vagina or in the adjacent cervix, benign cells of endocervical type may confuse the cytologic picture. In ulcerated tumors, evidence of inflammation and necrosis is usually present. Although the accurate diagnosis of vaginal carcinoma may not always be possible on cytologic evidence, **any significant cytologic abnormality in a young girl or woman warrants a careful colposcopic examination of the vagina.** While much less common now than when DES was prescribed during pregnancy, occasional instances of adenosis still occur and adenocarcinomas associated with adenosis are fully capable of metastasis.

Tumor Variants

As in the uterine cervix, we have observed a **coexisting adenocarcinoma and epidermoid carcinoma in situ in adenosis.** In this instance, the smear pattern was that of a low-grade squamous lesion and no cells of adenocarcinoma were present. Tissue evidence disclosed an epidermoid carcinoma in situ lining the surface of vaginal adenosis and, in the depth of the vaginal wall, an invasive adenocarcinoma (Fig. 14-9). A case of invasive **adenosquamous carcinoma** was described by Vandrie et al (1983).

Prognostic Factors

Fu et al (1979) attempted to establish the prognosis of the epidermoid and glandular lesions associated with DES exposure by measuring the **DNA content** of the component cells. These authors postulated that lesions of diploid or polyploid make-up have a higher chance of regression than

aneuploid lesions. As noted in Chapter 11 in reference to the uterine cervix, such measurements have limited value in the presence of permissive infection with HPV that modifies the DNA measurements (Chacho et al, 1990).

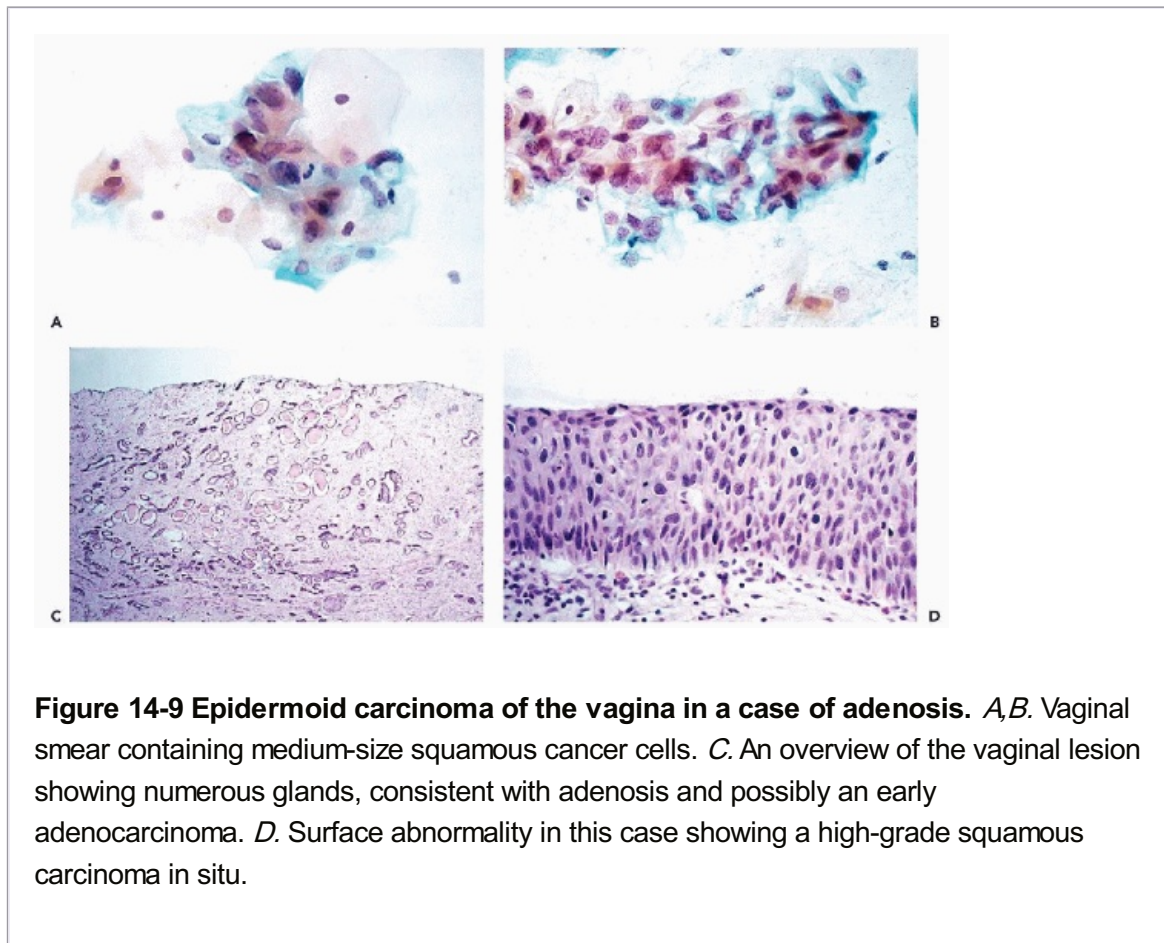

Figure 14-9 Epidermoid carcinoma of the vagina in a case of adenosis. *A,B.* Vaginal smear containing medium-size squamous cancer cells. *C.* An overview of the vaginal lesion showing numerous glands, consistent with adenosis and possibly an early adenocarcinoma. *D.* Surface abnormality in this case showing a high-grade squamous carcinoma in situ.

Uncommon tumors of the vagina are discussed in Chapter 17.

Lesions of the Neovagina

Neovagina or an artificial vagina may be constructed in women with congenital absence of vagina (Belleannée et al, 1998) or after surgical removal of vagina for a variety of reasons. The artificial vagina, whether constructed from skin grafts or an intestinal loop, usually becomes lined with squamous epithelium that may display a normal hormonal pattern. It is of particular interest that **squamous carcinoma** (summary in Rotmensch et al, 1983; Belleannée et al, 1998) or **vaginal intraepithelial neoplasia**, as reported by Lathrop et al (1985), may also be observed in neovaginas. The possibility that HPV infection may be a factor in such rare events was supported by the presence of koilocytes in vaginal smears of the patient described by Belleannée et al (1998).

Adenocarcinomas have also been observed in neovaginas **constructed from segments of the intestine** (Ritchi, 1929; Lavand'Homme, 1938). No recent reports of this very rare complication could be found.

Tumors of Bartholin's Glands

Tumors of the Bartholin's glands, located near the introitus in the posterior wall of the vagina, are generally not accessible to routine cytologic sampling except by needle aspiration. Thus,

Bartholin's gland **hyperplasias, adenomas, and cysts** have no known cytologic presentation in routine smears (Koenig and Tavassoli, 1998). Two cases of **malakoplakia** have been described (Paquin et al, 1986). For a detailed description of the pathology and cytology of this disease, see Chapter 22. However, the very rare **carcinomas of Bartholin's glands may break through the gland capsule into the vagina and occasionally yield malignant cells in cervicovaginal material**. Several such cases were reported (De Mauro et al, 1986).

Adenocarcinoma and adenoacanthoma, morphologically similar to carcinoma of the endometrium, are the most common types of malignant tumors. Several cases of **adenoid cystic carcinoma** have been described (Copeland et al, 1986) and one has been diagnosed on needle aspiration smears by Frable and Goplerud (1975). Cytologic presentation of adenoid cystic carcinomas is discussed in Chapter 32. A case of **squamous**

P.478

carcinoma, diagnosed in a vaginal smear, was reported by Gupta et al (1977). Other, very rare disorders such as **metastatic renal carcinoma** (Leiman et al, 1986) have been reported.

VULVA AND PERINEUM

Although the perineum is rarely the target of direct cytologic examinations, many of the vulvar lesions, discussed below, may also affect the adjacent perineum.

Histology

As discussed in Chapter 8, **the vulva** is composed of two sets of labia. There are basic structural differences between the epithelia of the vulvar external labia majora and the internal labia minora. The **labia majora** are lined by epidermis of the skin and contain the accessory apparatus thereof: hair, sebaceous glands, and sweat glands of the eccrine and apocrine type. The **labia minora** is an organ of transition between the skin of labia majora and the epithelium of the vagina. The squamous epithelium is not keratinized, resembles the lining of the vagina, and is free of hair; however, the subcutaneous tissue contains numerous sebaceous glands. The general configuration of the vulva depends on the **hormonal status** of the woman: it undergoes varying degrees of atrophy after the menopause. However, the epidermis of the labia majora does not show any cyclic changes. It is not known whether the epithelium of the inner surfaces of labia minora follows the cyclic changes occurring in the vagina (see Chap. 9).

The perineum is lined by skin.

Cytologic Sampling

It is generally considered that superficial scrape or cotton swab smears of the vulva have limited diagnostic value and that an energetic scraping with a wood or metal spatula is required to obtain a meaningful sample of cells. Dennerstein (1968) and Nauth (1986) recommended a **vigorous scrape of the vulvar lesions, if necessary, after removal of the layer of keratin** and claimed excellent diagnostic results in vulvar cancer.

Figure 14-10 Molluscum contagiosum of the vulva. *A.* Classical histologic aspect of this lesion with crevices filled with pox virus-containing cells. *B.* A scrape smear showing the particles of pox virus filling the entire cytoplasm of cells and pushing the nuclei to the periphery.

Normal Cytology

Smears of normal **labia majora** are **uniformly composed of anucleated squames and a minor population of nucleated superficial squamous cells**. Smears from **labia minora** more closely resemble vaginal smears and are **composed of nucleated squamous cells of various degrees of maturity**. Inflammatory cells are uncommon under normal circumstances.

Inflammatory Diseases

Herpes Genitalis

Herpes is commonly observed on the vulva and the clinical lesions are usually quite painful. Small vesicles filled with clear fluid or small, superficial ulcerations that are observed after the rupture of the vesicles are characteristic of the disease. Scrape smears of the lesions usually reveal the characteristic changes, described in Chap. 10.

Molluscum Contagiosum

A highly contagious pox virus causes pale, elevated and umbilicated lesions on the skin of the vulva. The lesions are composed of **large squamous cells filled with viral particles, coalescing to form large cytoplasmic inclusions that push the nucleus of the cell to the periphery (molluscum bodies)**. The molluscum bodies can be readily recognized in scrape smears of the lesions (Fig. 14-10).

Moniliasis of the vulva occurs mainly during pregnancy, in AIDS patients, and in diabetics. The fungus may be identified in scrape smears (see Chap. 10).

Other inflammatory diseases are usually sexually transmitted, such as **lymphogranuloma venereum** (caused by *Chlamydia trachomatis*) or **granuloma inguinale** (caused by *Calymmatobacterium granulomatis*) which may be observed on the vulva. The cytologic presentation of these disorders is described in Chapter 10.

pemphigus vulgaris. The vesicles, upon rupture, may yield the characteristic **Tzanck cells**, mimicking cancer, described in Chapters 19 and 21. Also of note is **vulvar involvement in Crohn's disease** in the form of ulcers (Freidrich, 1983; Holohan et al, 1988).

Lichen Sclerosus

This is a skin disorder of unknown etiology, affecting the vulva and the adjacent perineum. The disease has two forms: an **atrophic form** in which the squamous epithelium becomes thin and is accompanied by hyalinization of the underlying dermis, and a **hypertrophic form** in which the squamous epithelium is thickened (Ridley et al, 1989). It is thought that this disorder is a part of the spectrum of “**vulvar dystrophies**” that apparently predispose women to carcinoma of vulva. Van Hoeven et al (1997) described **cytologic findings** in a group of 29 patients with lichen sclerosus, six of whom had synchronous squamous carcinoma, either in situ or invasive. Besides the customary anucleated squames and nucleated squamous cells, these authors observed **elongated parabasal squamous cells** and, in some cases, atypical cells which, however, were insufficient for diagnosis of a malignant tumor in all but one case.

Benign Tumors

Except for condylomata acuminata (see below), benign tumors such as **granular cell myoblastoma**, **sweat gland adenoma**, **hidradenoma papilliferum** (Virgili et al, 2000), **ectopic breast tissue or fibroadenomas of mammary type** (Prasad et al, 1995) are usually subcutaneous in location and thus not accessible to cytologic sampling, except by aspiration biopsy.

Condylomata Acuminata

These are the most common benign tumors of the vulva, known to be caused by a sexually transmitted infection with human papillomavirus (HPV), usually types 6 and 11 but occasionally other types as well (see Chap. 11). The presence of HPV in condylomata acuminata can be documented with the use of the common viral antigen or by in situ hybridization with viral DNA of specific type under stringent conditions, as shown in Figure 14-15C, which documents the presence of a permissive infection with HPV type 11. Viral DNA is located mainly in the upper layers of the epithelium containing koilocytes. In two studies of condylomas from this laboratory, one conducted in children with anal lesions, and the other on penile condylomas in adults, the principal types of HPV observed were 6 and 11 but there were sporadic cases in which HPV 16 and 18 could also be demonstrated (Vallejos et al, 1987; Del Mistro et al, 1987) (see Chap. 11).

The wart-like tumors are usually multiple and may also involve adjacent areas of the skin, such as the perineum and the perianal area (Fig. 14-5C). Some lesions of this type grow to large sizes and **may show invasive and destructive growth**. It is often a matter of preference as to whether to classify such lesions as **giant condylomas** or as **verrucous squamous carcinomas**. They are usually associated with HPV type 11 and may also occur on the shaft of the penis, where they are known as **giant condylomas of Buschke-Löwenstein**.

Condylomata acuminata have traditionally been considered a benign disorder, although **recurrent condylomas and their progression to squamous carcinoma in situ** (Fig. 14-11B) **and to invasive squamous carcinoma have been recorded repeatedly** (Fig. 14-11C,D).

Many condylomas respond to treatment with the antimitotic agent, **podophyllin**, or the antiviral agent, **interferon**. The lesions can be removed by surgical resections or by **laser**.

Unfortunately, at least 20% of the patients fail to respond fully to these forms of treatment. Based on studies of immunologic events in response to HPV infection, an **immune-response modifier, imiquimod**, was isolated first from tissues of experimental animals, then in humans (Coleman et al, 1994). Imiquimod induces a number of cytokines and acts as an anti-viral and anti-tumor agent (Imbertson et al, 1998; Tying et al, 1998). Clinical experience in patients with anogenital condylomas showed a 50% response rate to 5% imiquimod cream (Aldara, 3M Pharmaceuticals, St. Paul, MN) (Edwards et al, 1998). One can anticipate that, in the future, other immunotherapeutic agents will become available that will prove to be more effective in the treatment of condylomas.

Histology of condylomas was discussed in Chapter 11. Suffice it to add that the presence of koilocytes in the upper layers of the epithelial lining is a common feature of these lesions. Few condylomas require **cytologic diagnosis**, but some of the flat forms of this disease may be so investigated, particularly in the **anal area** (see below). The cytologic presentation of flat condylomas of the cervix, dominated by koilocytes, is discussed in Chapter 11. Ward et al (1994) considered condylomas as a risk factor for cervical neoplasia and recommended cervical cytology and colposcopy as a routine procedure in such patients.

Malignant Tumors

Squamous Carcinomas

Squamous carcinomas are by far the most common malignant tumors of the vulva, usually involving the interior aspect of the labia majora but occasionally labia minora and the introitus. These tumors, and their precursors, are usually seen in women ages 40 to 60 (Jones et al, 1994). Within the last two decennia of the 20th century, a clear increase in younger women has been observed (Sturgeon et al, 1992; Joura et al, 2000). Vulvar cancer has also been observed in immunodeficient patients (Serraino et al, 1999). An invasive cancer of the vulva in a 12-year-old girl with HIV infection has been reported by Giaquinto et al (2000). Squamous carcinomas can be roughly divided into two groups, though intermediate-type lesions may occur:

- **Carcinomas with marked surface keratinization, akin to most squamous carcinomas of the skin and occurring mainly on labia majora. Verrucous carcinomas** are a variant of these tumors. **Koilocytosis is frequently**

P.480

observed in these tumors, suggesting origin from condylomas (Dvoretsky et al, 1984).

- The relatively uncommon, **highly malignant, poorly differentiated carcinomas composed of small cells, and often growing in solid sheets, mimicking basal cell carcinoma of the skin. Such lesions, also referred to as basaloid carcinomas, occur mainly on labia minora.**

Figure 14-11 Condylomas of vulva. *A.* The clinical aspect of the disease showing numerous wartlike structures surrounding the vulva. *B.* Histologic features of the surface epithelium of a lesion shown in *A.* *C.* Vulvar condyloma observed in 1962 and treated by local excision. *D.* Invasive squamous carcinoma in the same area of the vulva observed in 1969.

The information on HPV in vulvar carcinomas is contradictory. The presence of HPV sequences has been documented in some invasive carcinomas and in nearly all carcinomas in situ.

Although HPV types 6 and 11 have been shown to be associated with some vulvar carcinomas of verrucous type (see Chap. 11), subsequent studies suggested that the oncogenic types of HPV, namely types 16 and rarely 18, are associated with some but not all tumors (Toki et al, 1991). In a recent study, Logani et al (2003) observed prevalence of low risk HPV in these lesions, contrary to similar lesions in the vagina.

Cytogenetic studies of vulvar carcinomas disclosed a pattern of chromosomal abnormalities very similar to squamous cancer of the uterine cervix (Jee et al, 2001). Losses of the short arms of chromosomes 3 and 4 and gain in the long arm of chromosome 3 were also described in the uterine cervix (see Chap. 11).

Microinvasive Squamous Carcinoma

Microinvasive squamous carcinoma of the vulva is poorly defined. It is a matter of debate whether a depth of invasion of 1 or 3 mm is an acceptable criterion. Dvoretzky et al (1984) favored the depth of 3 mm as the best standard. Although the outcome of very superficially invasive carcinoma of the vulva is usually favorable (Wharton et al, 1974), there are sufficient cases on record of superficially invasive vulvar carcinoma with metastases to inguinal lymph nodes to consider such lesions as potentially lethal and deserving of aggressive treatment (Jafari and Cartnick, 1976; Nakao et al, 1974; Chu et al, 1982).

Cytology

Invasive squamous carcinomas are **warty or ulcerated**, or both, and most are identified clinically. Occasionally, however, **kraurosis vulvae**, extensive **herpetic vulvitis** or another

ulcerative process may imitate vulvar carcinoma and vice versa. In such situations, a scrape smear may help in establishing the diagnosis. It must be pointed out that the rare low-grade verrucous carcinomas of the vulva may have a thick layer of keratin on the surface and may not yield any identifiable cancer cells, unless the keratinized layer is removed.

Smears from invasive squamous carcinomas are often

P.481

partly obscured by inflammation and necrosis. Well-preserved cancer cells of squamous type are sparse and sometimes difficult to identify among anucleated squames. Quite often, only well differentiated dyskaryotic (dysplastic) cells may be observed with a cytologic pattern similar to condylomas (Fig. 14-12). The cytologic diagnosis of carcinoma of the vulva **may be difficult to establish** (Kashimura et al, 1993). **Therefore, the presence of atypical squamous cells with enlarged nuclei should lead to a request for a tissue biopsy risking, at times, a false alarm.** It may be noted that ulcerative lesions of the vulva, such as ulcers and herpetic vulvitis, may also yield atypical squamous cells. Tissue biopsy may be required to settle the diagnosis.

Figure 14-12 Invasive carcinoma of vulva with a smear pattern suggestive of condyloma. *A.* Spindly dyskaryotic (dysplastic) cells. *B.* Cells with features of koilocytes. *C.* Biopsy of vulva corresponding to *A* and *B* showing a lesion of squamous epithelium of the vulva with numerous koilocytes. *D.* Invasive squamous carcinoma of vulva adjacent to the lesion shown in *C*.

Predisposing Conditions

Atrophy of the vulvar skin, often associated with intense itch (**kraurosis vulvae**), excessive keratinization of vulvar skin (appearing as white lesions or **leukoplakia**), and **lichen sclerosus** are considered to be conditions predisposing to squamous carcinoma. Kraurosis vulvae shows atrophy of the epidermis, accompanied by an inflammatory infiltrate. In leukoplakia, the surface epithelium is covered with thick layers of keratin. Lichen sclerosus has been discussed above. The term “**vulvar dystrophy**” has been proposed to encompass a variety of lesions, including

lichen sclerosus, allegedly preceding vulvar carcinoma (Friedrich, 1976). Sagerman et al (1996) studied the distribution of HPV in 41 cases of “**vulvar dystrophy**,” 19 accompanying invasive squamous carcinoma and 22 not associated with cancer. Interestingly, the presence of HPV types 16 and 18 occurred in only 3 of 19 “dystrophies” accompanying cancer and in 12 of 22 of the lesions not associated with cancer. As the likelihood of progression of “dystrophies” to carcinoma is very small, this study, if confirmed, casts an uncertain light on the role of HPV in vulvar cancer.

Carcinoma In Situ of the Vulva (Bowen's Disease) and Related Lesions (Vulvar Intraepithelial Neoplasia; VIN)

Histology

Precancerous epithelial lesions of the vulva are now considered as a family of lesions known as vulvar intraepithelial neoplasia (VIN), which may be graded from I to III, as is the case for the cervical lesions (CIN) and vaginal lesions (VAIN). Alternately, the lesions can be classified as **low-grade and high-grade VIN**. One can consider **condylomata acuminata as low-grade lesions, keeping in mind their occasional role as a stepping stone to invasive squamous carcinoma**. Hart (2001) separated the vulvar lesions

P.482

into two groups: the classic Bowenoid VIN of different grades and a rare, extremely well differentiated variant that he called “simplex” or “differentiated type.”

The high-grade VIN may be subdivided into two types of lesions, corresponding to invasive squamous cancer:

- **The keratinizing variant, also known as Bowen's disease because of its resemblance to the identical lesion of the skin and to keratin-forming lesions (keratinizing carcinoma in situ) of the cervix and vagina.** The epithelium of the vulva is thickened and its surface is usually lined by a layer of keratin or by several layers of keratinized cells that may deceptively suggest a benign wart-like lesion. Occasionally, a **wart-like configuration of these lesions** may be observed. Scattered throughout the thickness of the abnormal epithelium are **cells with enlarged, hyperchromatic nuclei**. Some of these are very large. Mitotic activity is observed at all levels of the epithelium. Raju et al (2003) described a **pagetoid variant** of carcinoma in situ, containing large cells with clear cytoplasm, mimicking Paget's disease (see below).
- **Occasionally, high-grade VIN, particularly when located on labia minora, may be composed of small cancer cells and show little evidence of keratin formation on the surface.** Such lesions correspond to classical carcinomas in situ that are identical with poorly differentiated precancerous lesions of the vagina or the cervix.

Cytology

Most high-grade VIN are readily visible as either a “red” or a “white” lesion and the diagnosis should be established by biopsy. Occasionally, however, the clinical differential diagnosis between an inflammatory lesion, such as ulcerated herpetic lesions, a flat condyloma, a high-grade VIN, or an invasive carcinoma cannot be made and a scrape smear of the vulva is obtained.

Vulvar smears are often dry and the cells are distorted. Therefore, the interpretation of such material must be painstaking and careful. **In the presence of even a few squamous cells**

with large nuclei, further investigation by biopsy should be suggested. Even in well-preserved material, the cytologic presentation may be inconspicuous and the neoplastic lesion may be represented by a **few keratinized squamous cells with enlarged, hyperchromatic nuclei, in a setting of anucleated squames. This is particularly important in the recognition of keratinizing precursor lesions or cancer, particularly verrucous carcinoma.**

Poorly differentiated carcinomas of the vulva and their precursor lesions are uncommonly seen. The cells correspond to poorly differentiated carcinomas of the vagina or cervix (see Fig. 14-3 and Chap. 11).

There is no information on the cytologic presentation of microinvasive carcinoma.

Paget's Disease

Natural History and Histology

Paget's disease presents as an area of vulvar redness, sometimes associated with oozing of serous fluid from its surface. Actual ulceration is uncommon but may occur. This disorder, occurring in women above 40 years of age, must be considered in the differential diagnosis of inflammatory lesions, carcinoma in situ, and superficial malignant melanoma (see Chap. 17).

Similar to Paget's disease of the breast (see Chap. 29), the vulvar disease is associated with an **infiltration of the epidermis by large cells with clear cytoplasm and enlarged nuclei (Paget's cells)**. Large nucleoli may be present. Paget's cells may occur singly or in clusters, occasionally forming gland-like structures. Paget's cells may be spread along the ducts of sweat glands as well as hair shafts and hair follicles (Fig. 14-13C). Paget's disease of the vulva may spread to the perineum and even the perianal area, and, less commonly, the vagina. The cytoplasm of Paget's cells contains glycogen and mucin-like material that **stains intensely with mucicarmine**, a simple laboratory reaction helpful in the differential diagnosis from other lesions, particularly malignant melanoma.

It has been shown that some cases of Paget's disease of the vulva, like its breast equivalent, are associated with an underlying carcinoma of sweat glands, although the latter is sometimes very inconspicuous and difficult to identify (Koss et al, 1968). In many instances, however, **no underlying carcinoma can be found**; the pathogenesis of this type of Paget's disease is unknown. It should be noted that Paget's cells form desmosomal attachments to normal epithelial cells, a feature that appears to be unique to this disease (Koss and Brockunier, 1969). It is noteworthy that **metastatic carcinoma of the bladder to the vagina may mimic Paget's disease** (Koss, 1985; see Chap. 23). **Vulvar Paget's disease**, caused by spread of **bladder cancer**, was also reported by Wilkinson and Brown (2002). Staining with Uroplakin III antibody confirmed the urothelial origin of this disorder (Brown and Wilkinson, 2003).

The prognosis of Paget's disease depends on the depth of invasion and the presence of an underlying sweat gland carcinoma: if the latter is large, metastases to inguinal lymph nodes often occur. Still, even Paget's disease, without demonstrable underlying cancer, is often difficult to control, even by extensive surgical excision, and recurrences and spread to adjacent organs may occur. In an elaborate study of 21 cases, Crawford et al (1999) were unable to find any factors of predictive value.

Cytology

The diagnosis of Paget's disease of the vulva is usually based on biopsies. In fortuitous cases, in a scrape smear of the vulva or the adjacent vagina, **large, malignant cells with clear cytoplasm and enlarged, slightly hyperchromatic nuclei may be observed** (see Fig. 14-13). The cytologic findings are similar to those in mammary Paget's disease (see Chap. 29). The findings are not specific but the diagnosis may be suspected in an appropriate clinical setting. It is of note that **squamous cells in smears from Paget's disease may also show some nuclear atypia**. This feature, combined with the scarcity of cancer cells, may suggest a squamous carcinoma rather than Paget's disease. Few cases of Paget's disease with cytologic findings have been reported in the literature (Bennington et al, 1966; Masukawa and Friedrich, 1978;

P.483

Costello et al, 1988; Castellano Megias et al, 2002). They added very little to the above description.

Figure 14-13 Paget's disease of the vulva. *A,B.* Air-dried scrape smears of the surface of the lesion. Note cells with large nuclei and eosinophilic cytoplasm. The identity of the lesion shown in *C* cannot be recognized in these smears.

A case of **Paget's disease of the penis**, secondary to a sweat gland carcinoma, was described by Mitsudo et al (1981).

Bowenoid Papulosis

This disorder is characterized by **multiple, raised, pigmented (tan or brown) lesions of the skin of the genital area**, observed mainly in young male and female patients. The lesions are **histologically similar to Bowen's disease** but differ in behavior, inasmuch as they often disappear spontaneously and **do not progress to invasive cancer**. The presence of **HPV type 16** has been universally noted in these lesions, which are thought to constitute an important source of infection. The reason for behavioral differences between Bowen's disease and bowenoid papulosis is obscure at the time of this writing (2004). There is no information on the cytologic presentation of these lesions.

Other Tumors

The labia majora of the vulva may be the site of malignant tumors affecting the skin. We have observed a few **basal cell carcinomas** mistaken for other entities and, therefore, examined by scrape smears. Clusters of small, uniform, spindly cells with peripheral cells arranged perpendicularly to the main cell mass (palisading) are characteristic of this tumor. For further discussion of cutaneous tumors, see Chapter 34. A mammary **ductal carcinoma in situ**, derived from the vulva, was described by Castro and Deavers (2001). **Mammary carcinomas** derived from supernumerary breasts have also been described (Rose et al, 1990). Malignant melanomas and other uncommon tumors of the vulva are discussed in Chapter 17.

Male Partners of Patients With Vulvar Disorders

In principle, all male partners of women with condylomas or other forms of a permissive HPV infection should be examined because many of them will also be carriers of HPV and some may have **penile lesions** (Gross et al, 1985; Barrasso et al, 1987). Although visible penile lesions (**condylomas, bowenoid papulosis, carcinoma in situ, erythroplasia of Queyrat**) should be treated, there is no unanimity as to whether a colposcopic examination of the skin of the penis with laser treatment of minor skin abnormalities is warranted.

ANUS

Basic Concepts

As a corollary to the cytologic diagnosis of vulvar lesions, it has been observed that **precancerous lesions and cancers of the anus may be amenable to cytologic examination**. Patients at a high risk of neoplastic anal lesions are men and women engaging in receptive anal intercourse (Law et al, 1991), immunosuppressed patients infected with human immunodeficiency virus, patients with AIDS, organ transplant

P.484

recipients (summary in Palefsky et al, 1994; Frisch et al, 1997; Sillman et al, 1997; Goldie et al, 1999; Ryan et al, 2000). The presence of **human papillomavirus of various types appears to be the common denominator of the anal lesions** (Lowhagen et al, 1999; Palefsky, 1999). HPV type 16, particularly the HPV 16PL variant, appear to be associated with high-grade lesions (Frisch et al, 1997; Xi et al, 1998).

Anatomy and Histology

The outer aspects of the anus, and immediately adjacent portion of the anal canal, are lined by **squamous epithelium**. A narrow band of “**transitional epithelium**,” composed of several layers of small cells and having some resemblance to the urothelium (described in detail in Chapter 22), separates the squamous epithelium from the rectal mucosa. The **rectal mucosa** resembles the mucosa of the colon and is composed of tall, columnar, mucus-secreting cells, forming tubular crypts. For an excellent review of anatomy of this region, see Ryan et al (2000).

Benign Disorders

Disregarding vascular disorders such as hemorrhoids that are commonly observed, important diseases of the anus occur in men and women who practice anal sexual intercourse (Law et al, 1991). Infections with herpesvirus, Epstein-Barr virus, and human papillomavirus are more common in homosexual men than in women (Jacobs, 1976; Moscicki et al, 1999). Infection with

HIV and resulting AIDS are significant additional risk factors (Hillemanns et al, 1996; Palefsky et al, 1998; Lowhagen et al, 1999).

Figure 14-14 Anal lesions. *A.* Condyloma-like disease of squamous epithelium (*A*) with an underlying Kaposi's sarcoma (*B*) in a patient with AIDS. *C.* A poorly differentiated anal squamous carcinoma. *D.* A basaloid carcinoma of the anus.

The most common of these disorders is condylomata acuminata that may occur on the perianal squamous epithelium but also within the anal canal. These lesions are morphologically identical to vulvar condylomas, described above. In patients with AIDS, condylomas may be the site of **Kaposi's sarcomas** (Fig. 14-14A,B).

Malignant Lesions

Malignant lesions of the anus and their precursors (anal intraepithelial neoplasia, or AIN) resemble in many ways the lesions of the uterine cervix: **lesions derived from the squamous epithelium are well differentiated squamous carcinomas, some containing koilocytes in their surface epithelium and, hence, displaying features of condylomas**, in this example associated with Kaposi's sarcoma (Fig. 14-14C). Their precursor lesions resemble flat condylomas.

P.485

The highly malignant poorly differentiated carcinomas are derived from the “transitional epithelium” and resemble basaloid carcinomas or nonkeratinizing squamous (epidermoid) cancers (Fig. 14-14D). Their precursor lesions resemble squamous (epidermoid) nonkeratinizing high grade lesions derived from the epithelium of the endocervical canal (see Chapter 11). The terms **low-grade anal intraepithelial neoplasia (LGAIN)** and **high-grade anal intraepithelial neoplasia (HGAIN)** have been proposed to describe the precursor lesions of anal carcinoma (Lacey et al, 1999).

Palefsky et al (1990, 1998) observed that, in homosexual men with advanced AIDS, the anal neoplasia may develop over a short period of time. The same author (1999) noted that effective

antiviral therapy does not lead to regression of the neoplastic lesions.

Cytology

Methods

Moistened cotton swabs or plastic scrapers can be used to secure cell samples from the anus (Haye et al, 1988). It is unresolved whether the “adequate” sample must also contain glandular cells of the rectal mucosa. According to Sherman et al (1995) and Darragh et al (1997), such cells are more readily found in samples collected in liquid fixative than in conventional smears. Palefsky et al (1997) observed that the absence of such cells did not affect the sensitivity of the procedure.

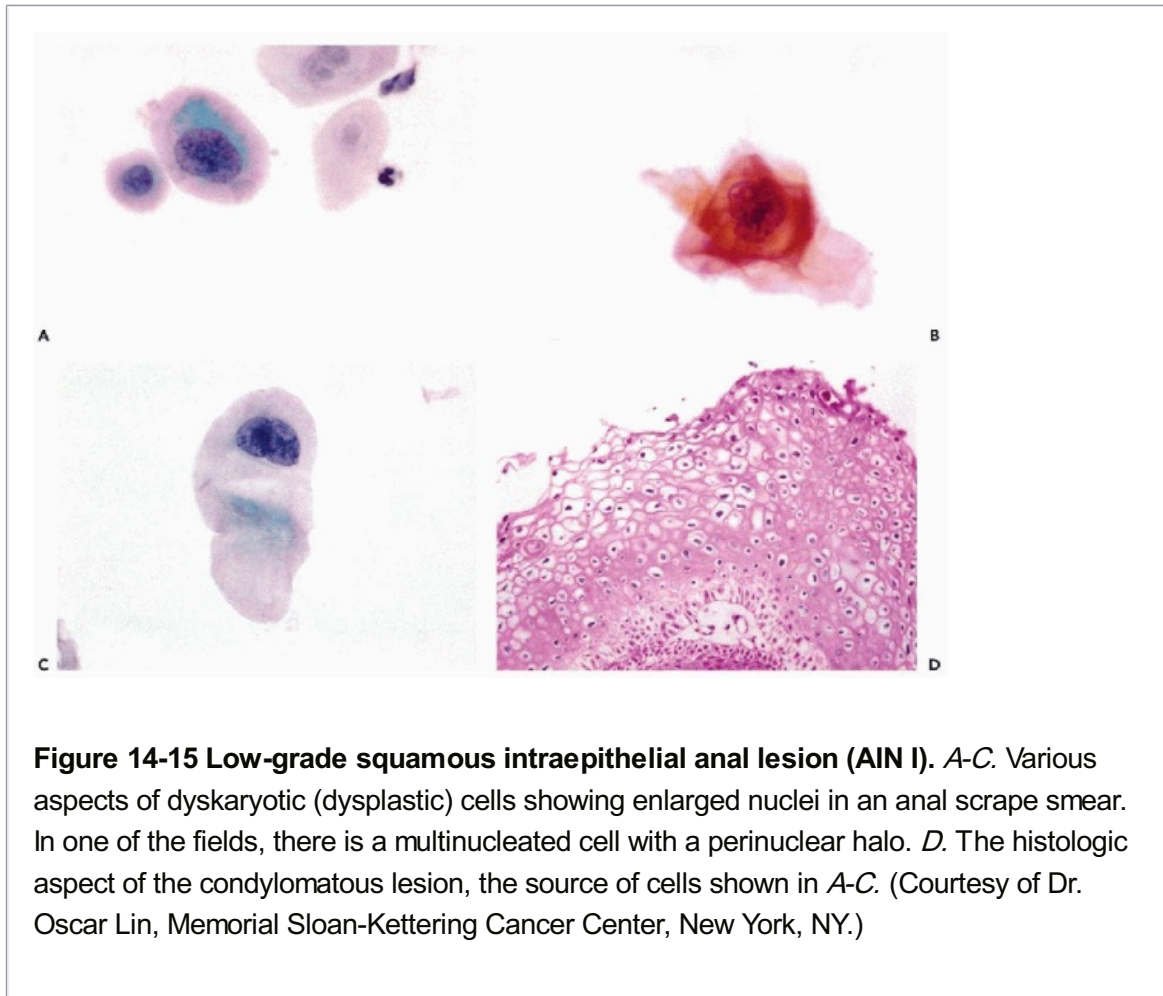

Figure 14-15 Low-grade squamous intraepithelial anal lesion (AIN I). A-C. Various aspects of dyskaryotic (dysplastic) cells showing enlarged nuclei in an anal scrape smear. In one of the fields, there is a multinucleated cell with a perinuclear halo. D. The histologic aspect of the condylomatous lesion, the source of cells shown in A-C. (Courtesy of Dr. Oscar Lin, Memorial Sloan-Kettering Cancer Center, New York, NY.)

Normal Anus

Smears of normal anus are identical to normal vulvar scrape smears and contain mainly anucleated and nucleated squamous cells. In specimens obtained from the anal canal, tall, columnar, mucus-producing rectal cells may be observed.

Inflammatory Disorders

Herpes genitalis may be observed in anal smears (Jacobs, 1976). There is no record of other identifiable infectious organisms known to us. For cytologic features of herpesvirus, see Chapter 10.

Precursor Lesions (AIN)

Low-Grade Lesions

Superficial squamous dyskaryotic (dysplastic) cells and koilocytes are the dominant cell types in perianal and anal condylomas (Fig. 14-15). These may be accompanied by

P.486

somewhat atypical squamous cells with enlarged nuclei. Smaller malignant squamous cells, similar to those observed in **high-grade lesions** derived from the endocervical epithelium, are characteristic of the high grade anal lesions (see Fig. 14-3). Scholefield et al (1998) observed a better reproducibility of diagnoses among pathologists with high-grade lesions than low-grade lesions.

Invasive Cancer

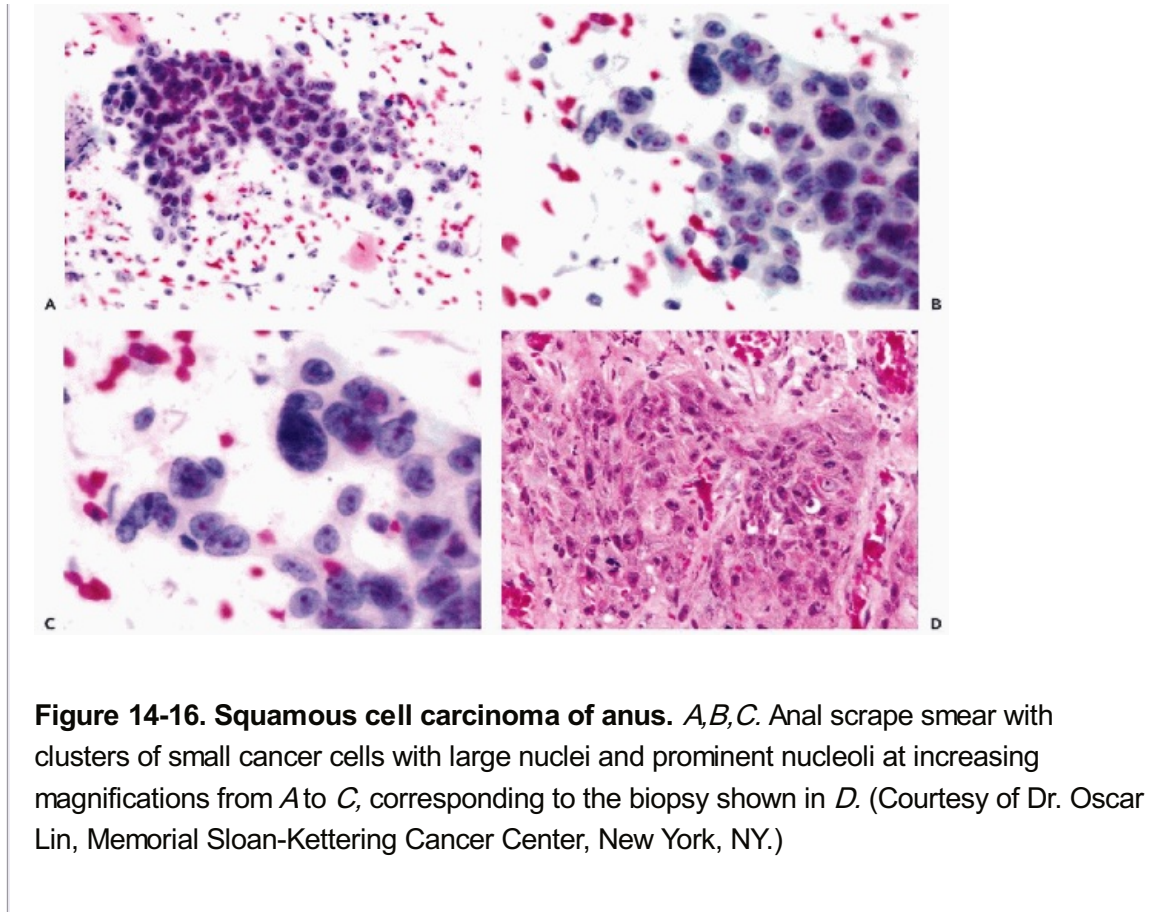

Invasive carcinomas of the anus, whether well or poorly differentiated, are morphologically identical to similar lesions of the vulva and vagina, described above. An example of a high-grade invasive carcinoma is shown in Figure 14-16.

Follow-Up of Cytologic Abnormalities

Colposcopy of the anus (anoscopy) followed by biopsies appears to be the method of choice to confirm cytologic abnormalities (Lacey et al, 1999).

Value of Anal Cytology

Anal cytology has now been accepted as a screening tool for anal neoplasia. The sensitivity of anal cytology (about 40% to 70% of the lesions, depending on the authors) is much greater than its specificity which appears to be about 40%. Palefsky et al (1997) emphasized the need for biopsy confirmation of abnormal findings. This **suggests that anoscopy and biopsies should be performed as a follow-up procedure of cytologic atypias, even in the absence of specific cytologic diagnosis** (De Ruiter et al, 1994). In one of the early papers on this subject, Sonnex et al (1991) compared the effectiveness of cytology, anoscopy, and in situ hybridization in the search for evidence of HPV infection and pointed out that anoscopy was more effective in the discovery of AIN than cytology. During the intervening years and improvement in sample collection, processing and interpretation the results have become more reliable. Perhaps the greatest value of anal cytology is in **situations when anoscopy is negative and cytology is suggestive or diagnostic of a neoplastic lesion**. Seven such cases were reported by Surawicz et al (1995).

Goldie et al (1999) studied the clinical- and cost-effectiveness of cytologic screening of homosexual and bisexual men infected with HIV. They concluded that the procedure is beneficial, cost effective, and comparable to other clinical preventive interventions.

Tumors of the Ovary and Fallopian Tube

THE OVARY

HISTOLOGIC RECALL

The anatomy of the ovaries was discussed in Chapter 8. Because components of the normal ovary may be observed in cytologic preparations, a brief summary of the histology is provided (Fig. 15-1).

The central portion of the ovaries is formed by the **hilum**, the site of entry of the vascular supply and lymphatic drainage. The **hilum** also contains **clusters of large endocrine cells with eosinophilic, granular cytoplasm**, similar to **Leydig cells** of the testis, that may contain rod-like Reinke's crystalloids. The ovary is surrounded by a **surface or germinative epithelium**. The bulk of the ovary is formed by **ovarian stroma**.

The **surface epithelium**, which is closely related to the mesothelium, is composed of a single layer of cuboidal cells with scanty basophilic cytoplasm and spherical nuclei. The surface epithelium often forms invaginations into the cortex of the ovary or **small cysts**. It should be noted that cortical cysts may be mistaken for ovarian follicles on ultrasound examination and may be incidentally aspirated during the harvest of ova for in vitro fertilization.

The **ovarian stroma** is composed of small spindly cells, some of which are capable of endocrine function. The superficial part of the ovarian stroma, **the cortex**, contains **ova** in various stages of maturation. The **ova**, numerous at birth, are reduced in number in the mature ovary and reside in the cortical stroma, where each ovum is surrounded by a single layer of epithelial cells, forming a **primitive follicle**. The maturation of the ova begins at puberty. Under the impact of **pituitary follicle-stimulating hormone (FSH)**, a few select follicles begin to enlarge. It is not known how and why the selection is taking place. The epithelial cells surrounding the ovum begin to multiply, become larger and multilayered, and are named **granulosa cells**. The ovum is separated from the granulosa cells by a homogeneous membrane, known as the **zona pellucida**. As the maturation of the ovum progresses, the number of cell layers of the granulosa increase. At the same time stromal cells surrounding the ovum become larger and, named **theca cells**, form a multilayered envelope around the follicle. The **granulosa and theca cells secrete estrogens** that induce the proliferative phase in the endometrium (see Chap. 13). As the follicle matures and enlarges, the granulosa cells form a cavity filled with a hormone-rich fluid. The ovum, still surrounded by granulosa cells, now protrudes into the follicular cavity;

P.492

the protrusion is named **cumulus oophorus** (Fig. 15-2A). At this point, the follicle is named after the Dutch anatomist who first described it in the 17th century, a follicle of **De Graaf or**

Graafian follicle. The graafian follicles are now visible on the surface of the ovary as small protrusions, but **normally only one of them will spontaneously rupture and discharge the mature ovum together with the follicular fluid into the peritoneal cavity**, followed by bleeding into the cavity of the follicle. Again, it is not known how and why the single follicle is selected. The ovulation takes place under the impact of **pituitary luteinizing hormone (LH)**, that also causes enlargement of the granulosa cells that converts the collapsed follicle into a **large, grossly visible yellow structure, the corpus luteum, that secretes progesterone**, thus inducing the secretory phase of the endometrium (Fig. 15-2B). The yellow color of the corpus luteum is due to a high lipid content of the hormone-producing component cells. The discharged ovum is captured by the fimbria of the fallopian tube, pending fertilization by a spermatozoon in the lumen of the tube. Unless pregnancy intervenes, the corpus luteum undergoes atrophy and fibrosis, resulting in a small **white scar [corpus albicans or (plural) corpora albicantia]** within the cortex of the ovary. If pregnancy occurs, the corpus luteum persists, becomes larger, and is known as **corpus luteum of pregnancy**.

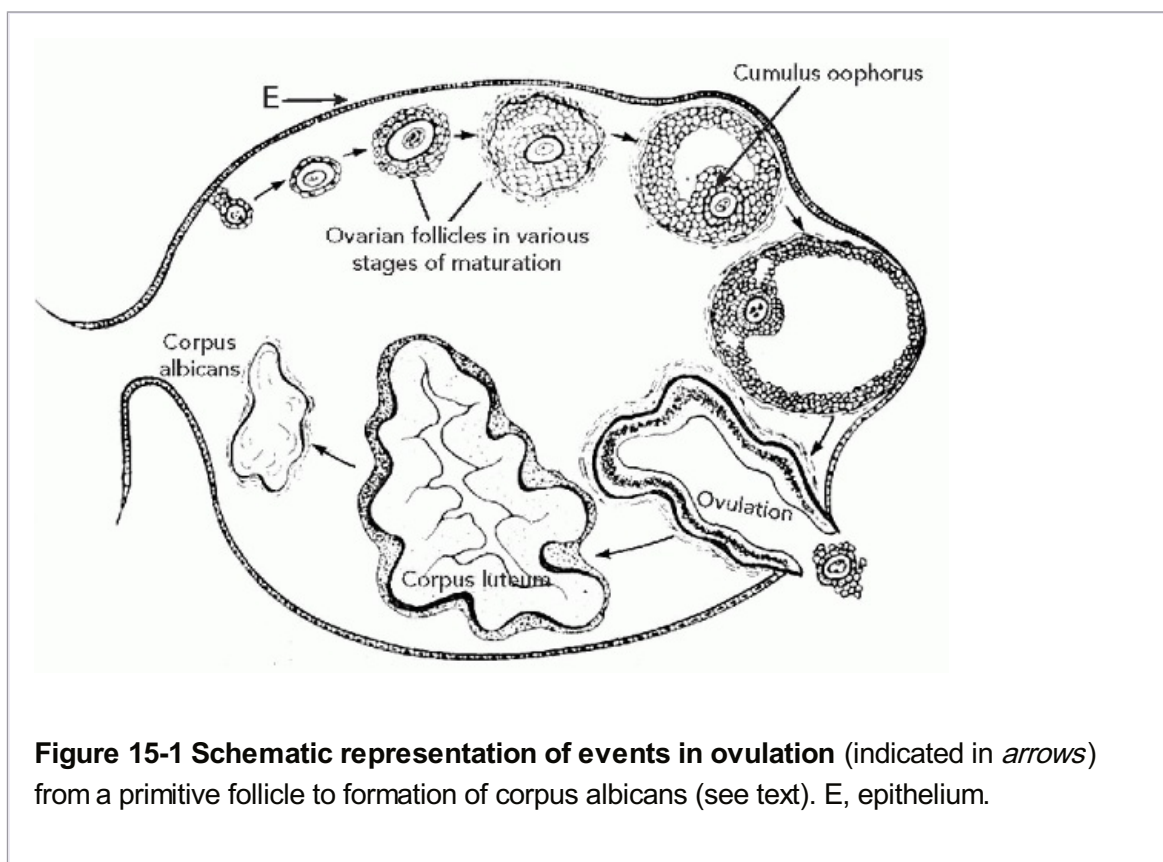

Figure 15-2 Graafian follicle (A) and corpus luteum (B). A. The follicle, lined by granulosa cells, contains fluid rich in estrogens. The ovum, still surrounded by a few layers of granulosa cells, protrudes into the follicle (**cumulus oophorus**). The granulosa cells are surrounded by layers of modified stromal cells, the **theca cells**. B. Corpus luteum composed of clusters of modified granulosa cells, secreting progesterone.

METHODS OF INVESTIGATION

Cervicovaginal Preparations

In the study of the ovary, cervicovaginal preparations may serve two purposes:

- They may contribute to the **diagnosis of ovarian tumors that shed recognizable cancer cells.**
- They allow an assessment of the **hormonal status of women, bearers of estrogen-producing tumors. This method occasionally contributes to the recognition of primary or recurrent tumors, particularly of granulosa cell tumors.**

Endometrial Aspirations

Occasionally ovarian tumors may be recognized in material aspirated from the endometrium. The techniques were described in Chapter 13.

Transvaginal Aspiration for In Vitro Fertilization

In vitro fertilization requires harvesting ova that are exposed to spermatozoa in vitro and then re-implanted into the suitably primed uterus. The ovary is stimulated by hormonal treatment to achieve maturation of several ova at the same time. The viable ova are harvested by ultrasound-guided transvaginal needle aspirates of maturing Graafian follicles (Fig. 15-3).

Cytologic examination of the aspirated material is not warranted unless the aspirated fluid is discolored or the amount is larger than the normal 2 to 3 ml (Greenebaum et al, 1992; Yee et al, 1994). When this occurs, it is assumed that either the aspirated follicle contained a blighted ovum or that a small cortical ovarian cyst has

P.493

been aspirated. **The main purpose of the cytologic examination is to identify benign or malignant cells in cysts, masquerading as follicles. It should be stressed that malignant tumors diagnosed during harvesting of ova are vanishingly rare** (Greenebaum et al, 1992; Rubenchik et al, 1996).

Figure 15-3 Ovarian puncture device. Automated, springloaded puncture device, with a 21-gauge needle attached, used to aspirate ovarian cysts under ultrasound guidance. (Drawing courtesy of Dr. Ellen Greenebaum, Columbia University College of Physicians and Surgeons, New York, NY.)

Aspiration Biopsy (FNA)

The purpose of direct ovarian aspiration is identification of the nature of cystic and solid tumors. The procedure can be performed **transvaginally** under ultrasound guidance or during **peritoneoscopy**. The general principles of the fine needle-syringe aspiration technique, or FNA, are discussed in Chapter 28. Initially, ovarian aspirates were performed using equipment devised for aspiration of the prostate (see Chap. 33 and Fig. 33-1). Currently, a **spring-loaded puncture device** with a 21-gauge needle attached to a collection trap is used for transvaginal aspirations (Fig. 15-3). For aspirations performed during peritoneoscopy, a small caliber needle attached to a syringe may suffice. With the progress in imaging, it is now possible to determine in advance whether the ovarian lesion is cystic or solid, or a combination of both.

The use of the aspiration technique for the diagnosis of malignant tumors of the ovary is highly controversial because of the danger of rupturing the capsule of a cancer, whether cystic or solid, and consequent spillage of malignant cells into the peritoneal cavity. The pros and cons of this technique have been well summarized by Greenebaum (1996). The advantages are a possible early diagnosis of ovarian tumors and avoidance of surgical procedures for benign cysts. De Crespigny et al (1989) and Greenebaum (1996) recommended that direct aspiration be limited to cystic lesions less than 10 cm in diameter without thick septa or solid areas on ultrasound imaging.

CYTOLOGY OF NORMAL OVARY

The normal cells that may be recognized in follicular aspirates obtained for purposes of in vitro fertilization are: **granulosa cells, theca cells, and ova.**

Granulosa Cells

Granulosa cells may be harvested from follicular cysts either before or after transformation into cells of corpus luteum (**luteinization**). The **nonluteinized granulosa cells** appear singly or in small, sometimes spherical (papillary) clusters, have a scanty eosinophilic cytoplasm and oval or bean-shaped nuclei that may show nuclear grooves (Fig. 15-4A). Mitoses may be observed. The nuclei are sometimes surprisingly large and hyperchromatic. There is usually a background of a few inflammatory cells, small macrophages, and debris. **Luteinized granulosa cells** are larger because of a more abundant, granular cytoplasm. The nuclei are sometimes in an eccentric position and are similar to nuclei of nonluteinized cells, except for the presence of visible chromocenters or small nucleoli (Fig. 15-4B) (Greenebaum, 1996; Selvaggi, 1996).

Smears with atypical granulosa cells may sometimes suggest a malignant tumor. The nuclei of such cells may be enlarged and granular, with larger nucleoli and may present a difficult problem of differential diagnosis. Selvaggi (1991) also stressed that the granulosa cell lining of some of the follicular cysts may be atypical and difficult to interpret. **Knowledge of clinical and ultrasonographic data is important in preventing diagnostic errors. Caution is advised before the diagnosis of a malignant tumor is made in such samples.** In a few such follicles, excised for verification of atypical cytologic findings, only benign ovarian structures were observed (Dr. Ellen Greenebaum, personal communication, 2003).

Theca Cells

The theca cells have not been identified with certainty. Greenebaum et al (1992) assumed that some of the smaller granulosa cells may represent luteinized theca cells. Selvaggi (1996) does not mention their existence in routine aspirates.

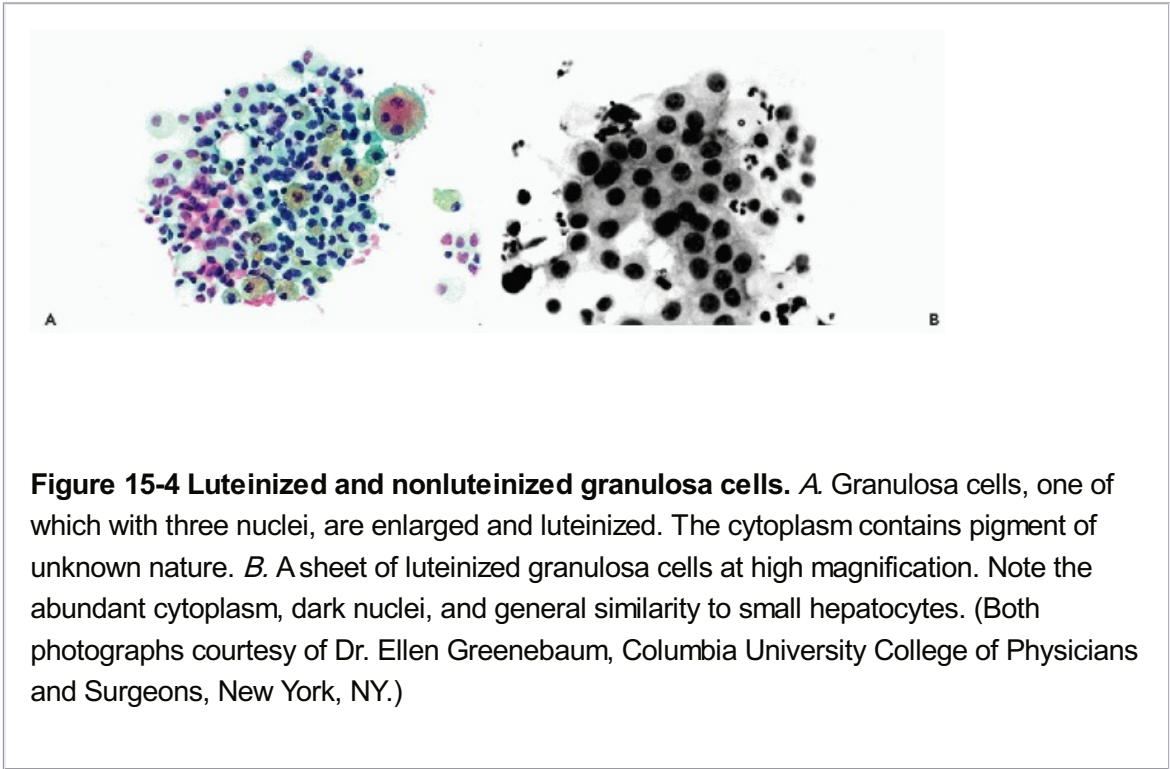

See Chapter 8 for comments on, and illustrations of, ova.

OVARIAN TUMORS

In spite of their modest size, the ovaries are the site of benign proliferative processes and of malignant tumors of a bewildering variety of histologic patterns, clinical behavior, and

P.494

significance. A description and discussion of all of these is beyond the scope of this work, and readers are referred to the authoritative reviews of this subject (Cannistra, 1993; Scully et al, 1998). Only tumors and tumorous conditions that have a cytologic correlation will be discussed here.

Tumors of the ovary are classified, on the basis of their origin, into several groups, listed in Table 15-1. From the point of view of diagnostic cytology, the most important are **cysts**, **malignant epithelial tumors** and **tumors with hormonal activity** (granulosa and theca cell tumors).

TABLE 15-1 SIMPLIFIED CLASSIFICATION OF OVARIAN TUMORS		
Tissue of origin	Epithelial tumors	
	Benign	Malignant
Germinative epithelium and its variants	Serous cysts (cystomas)	Serous carcinomas, Borderline (low malignant potential) serous tumors, Psammocarcinoma
	Mucous cysts (cystomas)	Mucous carcinomas, Borderline tumors
	Endometriosis Endometriotic cyst	Endometrioid carcinomas
	Brenner tumor	Malignant Brenner tumor, Clear cell (mesonephric) carcinomas

Rare types of carcinomas		
Granulosa-stroma cells		Granulosa cell tumor
Theca-stroma cells	Thecoma	Malignant variant extremely rare
Sertoli and Leydig cells (ovarian equivalent)	Hilar cell tumor	Sertoli-Leydig cell tumors (masculinizing)
Germ cells and embryonal structures	Benign teratoma (Dermoid cysts)	Malignant tumors derived from teratomas (carcinomas, carcinoid). Also dysgerminoma, Gonadoblastoma, Endodermal sinus tumor, Yolk sac tumor (Embryonal carcinoma)
Gestational trophoblasts		Choriocarcinoma
Very rare tumors	See Chapter 17	

Benign Ovarian Cysts

Benign ovarian cysts are by far the most common tumors of the ovaries. Besides follicular cysts resulting from events in ovulation, described above, benign cystic lesions of the ovary include **small cortical cysts**, caused by invagination of the surface epithelium, **corpus luteum cysts**, **cysts occurring in endometriosis**, and **serous or mucinous cysts (cystomas)**. The serous and mucinous cystomas may be monolocular or multilocular and may vary in size from tiny cysts, measuring a few millimeters in diameter, to very large cysts up to 20 or even more centimeters in diameter. **Corpus luteum cysts** are formed because of bleeding into the center of the corpus luteum. The **cortical inclusion cysts, serous cysts, and paraovarian cysts** are lined by small cuboidal cells, similar to the cells of ovarian epithelium (Fig. 15-5B). The **mucinous cysts** are lined by tall, columnar, mucus-secreting cells, akin to those lining the endocervical canal. Occasionally, both types of epithelia may be found side by side. **Endometriotic cysts** are usually formed by bleeding occurring in foci of endometriosis and usually contain liquefied blood and hemosiderin-laden macrophages in their center. Endometrial glands, sometimes accompanied by scanty endometrial stroma and hemosiderin-laden macrophages, are found in the wall of the cyst.

P.495

Cytology

Most fluids aspirated from benign ovarian cysts are **acellular**, as confirmed by Mulvany (1996).

The type of such cysts may be sometimes determined by biochemical studies of the aspirated fluid (see below). The cytologic evidence of cyst type is usually scanty and the precise type of cysts cannot always be determined. The description below is based on relatively few cases of benign cysts with diagnostic cellular features.

Figure 15-5 Ovarian cyst aspirates. *A.* aspirate from a simple serous cyst showing orderly clusters of small cuboidal cells in the background of squamous cells. *B.* Histologic section of the ovarian cyst represented in *A.* *C.* Aspirate of a paraovarian cyst in a 24-year-old woman. The smear shows squamous cells and small cuboidal cells assumed to be benign epithelial cyst lining. *D.* Aspirate of benign ovarian cyst in a young woman. The field shows monotonous macrophages. (*A,B* courtesy of Dr. Ellen Greenebaum, Columbia University College of Physicians and Surgeons, New York, NY; *D* courtesy of Dr. M. Zaman, New York Medical College, Valhalla, NY.)

Cortical Inclusion Cysts and Ovarian or Paraovarian Serous Cysts

These cysts may shed sheets of small, cuboidal cells with scanty cytoplasm and spherical, granular nuclei (Fig. 15-5A-C). **Ciliated epithelial cells** and ciliated cell fragments (**ciliated bodies**), are sometimes observed. Rivasi et al (1993) observed such cells in nearly 10% of aspirates from 320 ovarian cysts. Calcified debris or psammoma bodies may be present. For an extensive discussion of psammoma bodies, see below.

Greenebaum (1994) reported a case of a benign serous cyst with isolated, markedly atypical lining cells with large nuclei and a nondiploid DNA histogram. Occasionally the cyst fluid contains numerous macrophages (Fig. 15-5D).

Corpus Luteum Cysts

The aspirates from **corpus luteum cysts** may contain old, liquefied blood and foam cells (macrophages) and may be

P.496

difficult to distinguish from the contents of an endometriotic cyst (see below). The aspirates may

also contain **large, luteinized granulosa cells**. As has been noted above, such cells may be quite atypical because of large nuclei and nucleoli and may be confused with cancer cells. In a case reported by Burke et al (1997), the corpus luteum cyst occurred in an **ovarian remnant** after total abdominal hysterectomy and oophorectomy; the luteinized cells were mistaken for cancer cells.

Cysts of Unknown Derivation

In a personally observed case, the fluid from a benign cyst in a 17-year-old patient contained cells and cell clusters closely **resembling normal urothelium**, particularly multinucleated large cells resembling the superficial urothelial umbrella cells (Fig. 15-6A,B). It is possible, although unproven, that this cyst was related to a Brenner tumor (see below). The cyst also contained crystalline structures of unknown significance (Fig. 15-6C).

Mucinous Cysts

These may be occasionally recognized because of the presence of columnar, mucus-containing cells with small, basally located nuclei, similar to endocervical cells. The differential diagnosis between a benign mucinous cyst and a mucinous carcinoma (see below) may be impossible on cytologic evidence alone.

Endometriosis of the Ovary

Endometriosis is characterized by the presence of old, liquefied blood, **hemosiderin-containing macrophages**, and clusters of poorly preserved cuboidal epithelial cells of endometrial type. Endometrial stromal cells are very rarely seen.

Biochemical Studies of Fluids From Ovarian Cysts

Biochemical studies of acellular or cellular fluids aspirated from ovarian cysts may sometimes provide additional information on the nature of the cysts. Thus, estradiol-17 β is elevated in follicle cysts but not in other cysts (Geier and Strecker, 1981; Mulvany et al, 1995, 1996; Greenebaum, 1996). The antibody to the antigen CA125 may be elevated in a variety of benign and malignant lesions of the ovary. Carcinoembryonic antigen (CEA) may be elevated in mucinous ovarian tumors and in metastatic carcinomas of colonic origin (Pinto et al, 1990).

Figure 15-6 Ovarian cyst in a 17-year-old woman with lining suggestive of urothelial origin. A. Several clusters of fairly large epithelial cells with one flat surface. B. Multinucleated epithelial cells, closely resembling umbrella cells of urothelial origin (see Chapter 22).

Endosalpingiosis

Strictly speaking, endosalpingiosis **is not an ovarian disease**. It is described here because of its **important role in the diagnosis and differential diagnosis of ovarian tumors**.

Endosalpingiosis, a term first suggested by Sampson (1930), is defined as the **presence of multiple glandular cystic inclusions on the surface of the ovary, fallopian tubes, uterine serosa, and elsewhere in the pelvic peritoneum, omentum and even in pelvic lymph nodes**. Clement and Young (1999) described a rare form of **endosalpingiosis with tumor-like masses**, involving the uterus and rectum.

The cysts are lined by cuboidal or columnar epithelial cells, some of which are ciliated. Contrary to endometriosis, the cysts show no evidence of bleeding. Endometrial stromal cells are absent. The most important aspect of endosalpingiosis is the presence within the cysts of **numerous, concentrically calcified, approximately spherical structures, known as psammoma bodies** (Fig. 15-7). **In the presence of pelvic endosalpingiosis, psammoma bodies may also be observed in the endometrium and the endocervix**. It is not clear whether this phenomenon represents a transfer of psammoma bodies from the pelvic peritoneum to the uterus or represents “burned-out” foci of endosalpingiosis in this location. **In such cases, psammoma bodies may be observed in cervicovaginal samples**.

In the absence of an ovarian tumor, endosalpingiosis is a benign disorder; in the presence of an ovarian tumor, the possibility of metastases must be ruled out. For example, in 16 cases of endosalpingiosis, described by Zinsser and Wheeler (1982), there were four ovarian tumors that could have been a source of metastases. The significance of psammoma bodies in cytologic material is discussed below in reference to ovarian cancer and, in Chapter 16, to peritoneal

P.497

lavage. It must be noted that **calcified deposits** resembling psammoma bodies may also occur as an isolated event in **fallopian tubes and the endometrium** (Fig. 15-8).

Figure 15-7 Endosalpingiosis. *A.* Cyst lined with ciliated cells and containing calcified psammoma bodies on the surface of the fallopian tube. *B.* Fragment of endometriotic cyst with psammoma bodies in peritoneal wash specimen.

Primary Carcinomas

Epidemiology and Risk Factors

Cancer of the ovary is second only to carcinoma of the breast as cause of deaths among American women, with 23,100 new cases and 14,000 deaths projected for the year 2000 (Greenlee et al, 2000). The very high mortality from ovarian cancer reflects the dissemination of the tumor at the time of the diagnosis because of absence of symptoms in the early stages of the disease (Cannistra, 1993). The disease occurs mainly in women past the age of 40 with median age of 58 at the time of diagnosis. The overall 5-year survival rate is only 40% and is stage dependent. **Staging of ovarian carcinomas** is shown in Table 15-2. Stage I disease (confined to one ovary) offers a much higher survival rate than stage II to IV disease, the higher stages reflecting the degree of spread of cancer beyond the ovary of origin.

Various epidemiologic risk factors related to obstetrical, endocrine, and gynecologic events have been explored, none with conclusive results (Runnebaum and Stickeler, 2001). However, mutations in **breast cancer genes BRCA1 and BRCA2** constitute a **high risk factor** for familial ovarian carcinomas. The risk in women with BRCA1 mutations is the extraordinary 45% whereas for BRCA2 mutations, it is about 25% (summary in Runnebaum and Stickeler 2001). Ovarian cancers associated with BRCA1 mutation appear to have a more favorable clinical course when compared with sporadic cancers (Rubin et al, 1996). The presence of intratumoral T cells is apparently related to better survival (Zhang et al, 2003). It is of note that oral contraceptives may reduce the risk of ovarian cancer in these women (Narod et al, 1998).

Figure 15-8 Psammoma bodies in normal organs of the female genital tract. *A.* In endometrium. *B.* In fallopian tube. The finding in *B* is sometimes described as salpingolith.

Prophylactic salpingo-oophorectomy in women with BRCA1 or BRCA2 mutations repeatedly revealed small, occult ovarian cancers and other benign epithelial abnormalities (Salazar et al, 1996; Kauff et al, 2002; Stoler, 2002). Occult **carcinomas of the fallopian tubes and the peritoneum** also came to light in such studies. Agoff et al (2002) and Stoler (2002) emphasized the diagnostic value of peritoneal lavage in such patients (see Chap. 16).

P.498

An added advantage of prophylactic salpingo-oophorectomy appears to be a reduction in breast cancer (Kauff et al, 2002).

Early detection of ovarian carcinoma may conceivably improve the prognostic outlook. The current status of efforts toward early detection of ovarian cancer are summarized at the end of this chapter.

Classification

As shown in Table 15-1, the principal groups of ovarian carcinomas are:

- **Serous carcinomas**
- **Mucin-producing carcinomas**
- **Endometrioid carcinomas**

All these tumors may be cystic, solid, or a combination of the two presentations. Not uncommonly, the tumors involve both ovaries simultaneously.

Histology

Serous Carcinomas

These tumors usually originate from ovarian cysts lined by markedly atypical cuboidal epithelium that often forms papillary projections. The gland-forming tumors may range from borderline types, of relatively low malignant potential, to highly malignant, nearly solid tumors capable of distant metastases (Figs. 15-9B,D and 15-10D). A characteristic feature of these tumors is the formation of **calcified psammoma bodies** (calcospherites). Their diagnostic significance is discussed below. **Similar primary tumors may occur in the peritoneum** (see Chap. 26). A case of a peritoneal serous carcinoma in a patient with **BRCA1 gene mutation** was reported by Agoff et al (2002).

TABLE 15-2 STAGING OF PRIMARY CARCINOMA OF THE OVARY (FIGO)*

Stage	
I	Growth limited to the ovaries
Ia	Growth limited to one ovary; no ascites; no tumor on the external surface; capsule intact
Ib	Growth limited to both ovaries; no ascites; no tumor on the external surfaces; capsules intact
Ic†	Tumor either stage Ia or Ib, but with (1) tumor on surface of one or both ovaries or (2) capsule(s) ruptured or (3) ascites present containing malignant cells or (4) positive peritoneal washings
II	Growth involving one or both ovaries with pelvic extension
IIa	Extension and/or metastases to the uterus and/or tubes
IIb	Extension to other pelvic tissues

- IIc[†] Tumor either stage IIa or IIb, but with (1) tumor on surface of one or both ovaries or (2) capsule(s) ruptured or (3) ascites present containing malignant cells or (4) positive peritoneal washings
- III Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes (superficial liver metastasis equals stage III); tumor is limited to the true pelvis, but with histologically proven malignant extension to small bowel or omentum
- IIIa Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
- IIIb Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter; nodes are negative
- IIIc Abdominal implants > 2 cm in diameter and/or positive retroperitoneal or inguinal nodes
- IV Growth involving one or both ovaries with distant metastases; if pleural effusion is present, there must be positive cytology to allot a case to stage IV (parenchymal liver metastasis equals stage IV)

* Based on findings at clinical examination and/or surgical exploration. The histology is to be considered in the staging, as is cytology as far as effusions are concerned. It is desirable that a biopsy be taken from suspicious areas outside of the pelvis.

[†] To evaluate the impact on prognosis of the different criteria for allotting cases to stage Ic or IIc, it would be of value to know: (1) if rupture of the capsule was (a) spontaneous or (b) caused by the surgeon, or (2) if the source of malignant cells detected was (a) peritoneal washings or (b) ascites. (From McGowan L. Peritoneal fluid washings [letter to editor]. *Acta Cytol* 33:414-415, 1989.)

Borderline Serous Tumors

This is a well-differentiated variant of papillary serous adenocarcinoma, with orderly epithelium, resembling vaguely the histologic structure of the fallopian tube. Such tumors were previously classified as *endosalpingiomas* but today the preferred term is “**borderline serous tumors**” or serous tumors of “**low malignant potential**” (Fig. 15-11).

Separation of borderline serous tumors from serous carcinomas is the subject for a considerable debate (Scully et al, 1998; Prat, 1999). In general, the borderline tumors are composed of cysts and well-differentiated papillary structures lined by one or two layers of uniform cuboidal or columnar cells, that do not invade either the stroma of the tumor or the adjacent ovary. The prognosis of the tumor is usually very good with long-term survival of about

90%, although late recurrences may be observed.

A fairly common event in these tumors is the presence of **tumor deposits** or “implants” on the **serosal surfaces of adjacent organs**, the peritoneum and the omentum. The deposits are classified as either **invasive** or **noninvasive**. In the invasive deposits, there is obvious spread of the tumor cells to the adjacent fat or connective tissue. In the noninvasive

P.499

deposits, the tumor nodules are circumscribed implants on serosal surfaces. The nature of the deposits is enigmatic and many of them may represent synchronous primary events in the serosal surfaces rather than true metastases. Seidman et al (2002) explored the possibility that the “implants” may be somehow related to chronic salpingitis with psammoma bodies, named salpingoliths. The deposits may contain **numerous psammoma bodies** that may be either sparse or absent in the primary tumor. In any event, the prognosis of borderline serous tumors is much less favorable if the serosal deposits are invasive (summary in Prat, 1999). The same observation pertains to **tumor deposits in regional, usually paraortic, lymph nodes**. Many of these deposits are probably benign glandular inclusions of no prognostic significance but some represent real metastases (Prade et al, 1995; Moore et al, 2000).

Figure 15-9 Ovarian serous carcinoma in cervicovaginal smears. A,C. large compact papillary clusters of tightly packed large malignant cells corresponding to the ovarian serous carcinomas shown in B and D.

Psammocarcinomas

A group of serous carcinomas exceptionally rich in calcified psammoma bodies has been identified as tumors with better prognosis than the common serous cancer and named **psammocarcinomas** (Gilks et al, 1990). My old chief, Dr. Fred Stewart, believed that psammocarcinomas may be selfhealing or “burnt out,” serous carcinomas, leaving behind collections of psammoma bodies. The tumor may be related to **endosalpingiosis**, described above.

Peritoneal Mimickers of Ovarian Serous Carcinomas

It has also been observed that **tumors mimicking ovarian serous carcinomas may originate in the peritoneum**. Various names have been applied to this group of rare tumors: **peritoneal papillary serous carcinoma, multifocal extraovarian serous carcinoma, and serous surface papillary carcinoma** (review in Mills et al, 1988). **Borderline lesions** of this type may also occur (Bell and Scully, 1990). The survival of patients is very poor, probably because these rare tumors are disseminated at the time of diagnosis. The cytologic presentation of such tumors in fluids is similar to that of primary ovarian tumors (see Fig. 16-8).

Mucin-Producing (Mucinous) Carcinomas

These tumors usually originate in ovarian cysts and are usually multiloculated. The mucinous tumors may reach very large sizes and their surgical removal with intact capsule should be curative of the disease. Usually, the epithelial lining resembles **intestinal epithelium rich in goblet cells, occasionally containing Paneth cells**. In some tumors, the epithelial lining resembles the **endocervical epithelium** in the form of **tall, columnar, mucus-producing cells with relatively small, spherical, basally-placed nuclei**. The number of cell layers and level of nuclear abnormalities are the criteria of separation between the benign, borderline

P.500

or fully malignant tumors but are not always valid (Fig. 15-12).

Figure 15-10 Ovarian serous carcinoma in cervicovaginal material. *A* A cluster of malignant cells of variable sizes corresponding to a poorly differentiated serous carcinoma of the ovary. This presentation is unusual and not characteristic of ovarian tumors. *B, C.* Psammoma bodies in vaginal smears in the presence of serous carcinoma of the ovary shown in *D*. Note that the psammoma body shown in *B* is surrounded by large malignant cells. In *C*, the psammoma body occurred in a papillary cluster of malignant cells. *D.* Serous carcinoma of the ovary showing numerous psammoma bodies.

The mucinous tumors, even with a low grade of nuclear abnormality, may spread to the

abdominal cavity, particularly if inadvertently ruptured during removal or sampling. The characteristic pattern of spread of the tumors is on the surfaces of abdominal viscera, particularly the omentum and the intestinal serosa. The resulting lesion is accompanied by ascites, is **akin to pseudomyxoma peritonei**, described in Chapter 26, and does not respond to treatment. It has been shown that **similar tumors may synchronously occur in the appendix** and may be the source of peritoneal spread (Young et al, 1991). Molecular evidence suggests that most **pseudomyxomas are of appendiceal origin** (Szych et al, 1999). **Mural nodules**, that may have the configuration of poorly differentiated sarcomas, may be observed in the wall of mucinous tumors.

Borderline Mucinous Tumors

This is a poorly defined group of ovarian neoplasms characterized by focal nuclear abnormalities in the multilayered lining of multiloculated mucinous cystic tumors (Fig. 15-12C). Their behavior depends on the preservation of their capsule. Late recurrences have been observed (summary in Prat, 1999). Peritoneal implants may also be observed in such tumors.

Endometrioid Carcinomas

These tumors are presumably derived from areas of endometriosis, although this origin is often difficult to prove. Histologically, the tumors **resemble endometrial carcinomas in all their various forms** (see Chap. 13). Squamous differentiation within the tumor is common, and it may range from small foci with squamoid features (**adenoacanthoma**) to tumors with a poorly differentiated squamous component (**adenosquamous carcinoma**). While glandular features are usually present, solidly growing tumors may occur. Synchronous occurrence of the ovarian tumors of this type with endometrial carcinomas has been repeatedly observed.

Rare Types of Ovarian Carcinoma

Tumors resembling the so-called **clear cell carcinomas** of the cervix and vagina (see Chaps. 11 and 14) are well known and are sometimes still referred to as “**mesonephric**” tumors.

Small cell carcinoma is a rare tumor resembling oat cell carcinoma of the lung (Dickersin et al, 1982; Eichhorn et al, 1992). In about two-thirds of the cases, there is an elevation

P.501

of serum calcium (**hypercalcemia**). Young et al (1994) stressed that the **differential diagnosis** of these tumors includes **granulosa cell tumor** and an ovarian involvement by **abdominal small round cell desmoplastic tumor**, discussed in Chapter 26.

Figure 15-11 Borderline serous tumor of ovary in a 50-year-old woman. *A.* A tightly packed cluster of small malignant cells containing a large psammoma body. *B.* Gross appearance of the ovaries upon removal. Note tumor growth on the surface of the ovary. *C.* A very well differentiated borderline serous tumor of ovary. *D.* The tumor has spread to the adjacent omentum which shows numerous psammoma bodies. After removal of the ovaries and the omentum, the patient was free of disease for 10 subsequent years. (Case courtesy of Dr. Short, Chicago, IL.)

Carcinomas originating in ovarian teratomas are predominantly of squamous type. Malignant carcinoids and thyroid carcinomas can also occur in teratomas (Baker et al, 2001). **Ovarian squamous cancers not occurring in teratomas are rare** (Pins et al, 1996). **Yolk sac (or endodermal sinus tumors) and embryonal carcinomas of the ovary** occur mainly in children and young adolescents. Malignant tumors with hormonal activity are described below.

Tumors of mesothelial lining of the ovary (**ovarian mesotheliomas**) are discussed in Chapter 26.

Cytology

Cervicovaginal Samples and Endometrial Aspirations

In about 20% to 30% of patients with **advanced** ovarian carcinoma, regardless of histologic type, **malignant cells** may be observed in cervicovaginal preparations and occasionally in endocervical and endometrial aspirates (Jobo et al, 1999). Conversely, the presence of ovarian cancer cells in cervicovaginal smears usually, but not always, indicates advanced disease. The cancer cells may be derived from a primary tumor, via the fallopian tubes and the endometrial cavity, but may also reflect metastatic foci either within the endometrial cavity or in the vagina.

When seen in cervicovaginal smears or in endometrial aspirates, the tumor cells of nearly all ovarian cancers form **clusters, often of papillary configuration, made up of large malignant cells with prominent, large nuclei, containing multiple, often large, irregular nucleoli** (see Fig. 15-9). Single, usually large cancer cells with hyperchromatic nuclei

containing large nucleoli may also be observed (see Fig. 15-10A). **Cytoplasmic vacuoles** are fairly common but may be the **dominant feature of cells derived from the relatively uncommon mucinous cystadenocarcinomas** (see Fig. 15-12A). The latter may also shed cells of **columnar configuration**. As a general rule, **cancer cells of ovarian origin are larger than cells of endometrial origin**, but there are exceptions. The exact identification of histologic type of carcinoma in cytologic material is not always easy.

P.502

The most helpful hint is offered by **psammoma bodies**, concentrically calcified, spherical structures of various sizes.

Figure 15-12 Mucinous adenocarcinoma and mucinous borderline tumor with recurrence. *A.* Direct aspirate of a mucinous cystadenocarcinoma of the ovary showing, at its periphery, tall, columnar, mucus-producing cells. *B.* The ovarian tumor corresponding to *A.* *C.* Borderline mucinous tumor of ovary in a 38-year-old woman observed in 1985. *D.* A cell block of an aspirated cul-de-sac nodule of the same patient in 1995. The nodule, with malignant features, retains some resemblance to the original mucinous tumor.

Psammoma bodies are commonly found in **serous carcinoma of the ovary**, less commonly in the **borderline serous tumors**, very rarely in **endometrioid carcinomas**, and practically never in mucous tumors. It must be noted that **primary endometrial carcinomas may occasionally form psammoma bodies** (see Chap. 13).

When observed in cytologic preparations, psammoma bodies either are accompanied by cancer cells or are found isolated. In **high-grade serous carcinomas**, the psammoma bodies are usually accompanied by readily identifiable **large cancer cells**, as described above (see Fig. 15-10B,C). In such cases, there are usually no problems of cancer identification. In **borderline serous tumors**, the cells accompanying the psammoma bodies are smaller and are arrayed in tightly packed papillary clusters (see Fig. 15-11A). The number of cells in such clusters is very variable, ranging from a few to several hundred. The nuclear abnormalities are relatively inconspicuous, and the nucleoli are small. The finding of psammoma bodies accompanied by cancer cells is suggestive of tumor spread beyond the ovary, even in the

absence of clinical symptoms.

Endosalpingiosis is the most important entity in the differential diagnosis of serous ovarian carcinomas with which it shares the presence of numerous psammoma bodies in cervicovaginal smears and other cytologic preparations (see Fig. 15-7). In this condition, the psammoma bodies are either isolated or sometimes accompanied by a few small epithelial cells. These rare events may cause a great deal of diagnostic difficulty because they mandate a search for an ovarian carcinoma. Kern (1991), on review of nearly 10,000 cervicovaginal smears, noted that the presence of psammoma bodies was **more common in benign conditions (i.e., endosalpingiosis) than in ovarian carcinoma**. In a more recent study, Parkash and Chacho (2002) observed that over one half (11 of 20) of cervicovaginal smears containing psammoma bodies came from patients without cancer. **Also, calcified fragments of IUDs, some mimicking psammoma bodies, have been observed in patients wearing intrauterine contraceptive devices** (see Chap. 10), but the fragments are usually small and unstructured, lack the characteristic concentric lamination and are not accompanied by cancer cells. They may, however, be surrounded by macrophages.

Still, the presence of psammoma bodies in a cervicovaginal preparation or in an endocervical or endometrial aspiration, particularly in the absence of an intrauterine

P.503

contraceptive device, calls for a thorough investigation of the female genital tract to rule out a malignant tumor, most likely of ovarian origin. For a discussion of psammoma bodies and calcified debris in peritoneal washings, see Chapter 16.

Takashina et al (1988) compared the performance of **cervicovaginal smears and endometrial aspirates** in 114 patients with clinically documented **ovarian cancer** of various types and stages. The cervicovaginal smears were positive in 19% of the patients. Cancer cells were also found in 13 of 31 (42%) endometrial aspiration smears. The presence of ascitic fluid increased the rate of positive smears. Jobo et al (1999) confirmed that satisfactory **endometrial aspirations** provided diagnostic material in about 25% of 210 patients with ovarian cancer. The results were stage dependent: the smears were diagnostic of cancer in 3.9% for stage I tumors and over 50% in stage IV. It is of incidental interest that two occult ovarian serous adenocarcinomas were also observed by us during the search for occult endometrial cancer (see Chap. 13 and Fig. 15-10C,D). In both instances, the cancer cells were identified in vaginal pool smears and in direct endometrial samples.

Direct Needle Aspirates (FNA) of Ovaries

The methods of aspiration were discussed above. Direct aspirates from ovarian carcinomas are, as a rule, richer in cells than are aspirates from benign epithelial tumors. The cytologic recognition of a malignant tumor is usually not difficult. Even in well-differentiated types of carcinoma, the smeared aspirate contains approximately **spherical (papillary) groups of cancer cells, often with characteristic nuclear features, such as enlargement and hyperchromasia, large nucleoli, and thickening of the nuclear membrane** (Fig. 15-13). In **serous adenocarcinoma**, the cells may form a monolayer, but such a finding is insufficient for a reliable distinction between a serous and endometrioid carcinoma. Psammoma bodies are rarely seen in direct aspirates. **Mucinous ovarian carcinoma** may be recognized by the presence of **mucus-producing columnar cells embedded in masses of mucus** (see Fig. 15-11A). **Clear cell adenocarcinomas** may resemble clear cell adenocarcinoma of the kidney (see Chap. 40).

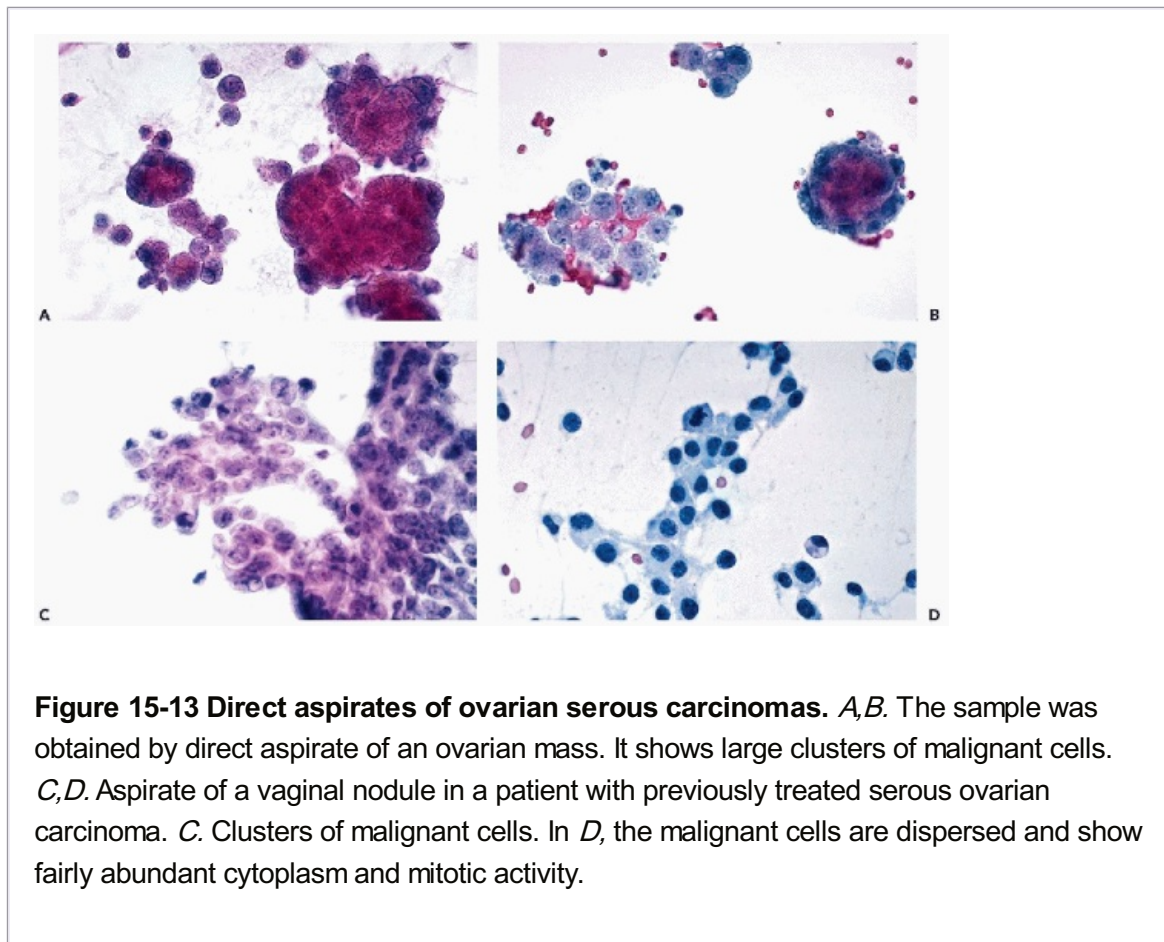

Figure 15-13 Direct aspirates of ovarian serous carcinomas. *A,B.* The sample was obtained by direct aspirate of an ovarian mass. It shows large clusters of malignant cells. *C,D.* Aspirate of a vaginal nodule in a patient with previously treated serous ovarian carcinoma. *C.* Clusters of malignant cells. In *D*, the malignant cells are dispersed and show fairly abundant cytoplasm and mitotic activity.

In serous lesions of “**borderline malignancy**,” the needle aspirates usually are more cellular than in benign cystomas, often forming **large flat clusters of well-adhering cells with only slight nuclear enlargement and minimal hyperchromasia**.

The accuracy of aspiration biopsy cytologic diagnosis in patients with ovarian enlargement or cancer was reported by Kjellgren and Ångström (1971, 1979), Geier et al (1975), Nadji et al (1979), and Geier and Strecker (1981). In these reports, ovarian cancer was accurately identified in

P.504

approximately 85% to 90% of cases. The proportion of false-positive cytologic reports in histologically benign lesions varied from 0% to about 5%. None of these authors reported on spread of tumor cells after the procedure. The caveats pertaining to this method of diagnosis of ovarian tumors were discussed above.

Tumors With Hormonal Activity

Theca and granulosa cell tumors, or a combination thereof, usually originate in cells forming ovarian follicles. It is quite likely that at least some of them originate in the ovarian stroma. These tumors may occur in all age groups, although they are uncommon in children. **Theca cell tumors** are grossly solid and hard and are made up of bundles of elongated, spindly cells resembling fibroblasts. The tumor is rich in cholesterol and other fats, which usually gives it a yellowish hue on section. Theca cell tumors are benign with very rare exceptions (Yang and Mesia, 1999). **Granulosa cell tumors**, which may be either benign or malignant, are generally soft and fleshy and have a number of different histologic patterns. These tumors are principally composed of small or medium-sized cells forming nests or sheets and sometimes **rosette-like**

clusters resembling primitive follicles, known as the **Call-Exner bodies**. **Nuclear folds or “grooves”** are commonly observed in these tumors. Many uncommon histologic variants of this tumor have been recognized (Scully et al, 1998). Granulosa-theca cell tumors show a combination of both tumor types.

Most, although not all, of these tumors have marked **hormonal activity**, usually of estrogenic type. Occasional cases of masculinization have also been recorded with these tumors, hence a testosterone-like metabolic pathway may occur. The estrogenic function of the theca and granulosa cell tumors may be reflected in the morphology of the endometrium and in the squamous epithelium of the vagina and the cervix. **Endometrial hyperplasia and endometrial carcinoma** are known complications of these tumors, as discussed in Chapter 13.

Cytology

Cervicovaginal Smears

Hormonal Patterns.

The cytologic identification of the hormonal effect on the squamous epithelium depends on the age of the patient. **In a woman of childbearing age**, it is extremely difficult to detect increased estrogenic effect on a single vaginal smear. However, if serial smears, as described in Chapter 9, show a consistent preovulatory (estrogenic) pattern, an abnormality of the estrogen output may be suspected. **In children and in postmenopausal women**, the presence of a very high level of maturation of squamous cells in a vaginal smear is suggestive of an **abnormal estrogen activity, which may be caused by an estrogen-producing ovarian tumor**.

Granulosa and granulosa-theca cell tumors have an unpredictable behavior and may recur and even metastasize, sometimes several years after the removal of the primary lesion. The **recurrent tumors** may also be estrogen producers and may be **heralded by an estrogenic smear pattern**, which is particularly evident in postmenopausal women (Fig. 15-14A,C). On rare occasions, **other ovarian tumors** such as mucinous cystadenoma, may also show luteinization of ovarian stromal cells and have an **estrogenic effect** on smears.

Masculinizing tumors of the ovary (Sertoli and Leydig cell tumors, hilar cell tumors, gonadoblastomas) have occasionally been recorded as **suppressing the maturation of squamous epithelium**, resulting in low estrogenic level in smears during the childbearing age (Rakoff, 1961).

Tumor Cells.

In rare cases of **malignant granulosa cell tumors** with disseminated metastases, malignant cells of variable sizes with scanty cytoplasm and hyperchromatic nuclei with fairly large nucleoli have been observed in cervicovaginal smears. In the absence of history or clinical data, the precise classification of the tumor cannot be established.

Aspiration Biopsy (FNA)

Needle biopsy usually yields preponderantly granulosa cells. Granulosa cells appear in smears in **variable-sized clusters of medium-sized cells with granular cytoplasm and monomorphic, coffee-bean shaped oval nuclei, with inconspicuous nucleoli** (Fig. 15-15D). **Nuclear “grooves”** are common and have been repeatedly reported in metastatic granulosa cell tumors (Ehya, 1986; Ali, 1998; Thirumala et al, 1998). Zajicek observed that the

presence of mitotic figures is suggestive of a malignant variant of the tumor.

Yang and Mesia (1999) reported a case of an extremely rare **malignant fibrothecoma** of ovary. The aspiration biopsy smears disclosed tightly packed small cells with uniform nuclei, diagnosed as "low-grade neoplasm."

Germ Cell Tumors

Benign Germ Cell Tumors

Benign Teratomas

Benign germ cell tumors are ovarian teratomas, also known as **dermoid cysts**. The tumors, usually observed in young women, are often bulky and composed of a **variety of tissues derived from two or three embryonal layers**, including skin and its appendages which are often the dominant component (hence the name dermoid cyst), brain tissue, gut, lung, thyroid etc. **So-called monomorphic teratomas** contain only one tissue type, such as the thyroid (**struma ovarii**).

Cells derived from benign teratomas have never been observed in routine cervicovaginal material. The diagnosis may be established or suspected in direct aspirates.

The aspirates of dermoid cysts usually contain **smelly amorphous matter (sebum) mixed with squamous epithelial cells and inflammatory cells, including foreign body giant cells**. Equally characteristic is the presence of **hairs**, provided that contamination of the smear by skin hair can be ruled out (Kjellgren and Ångström, 1979). The presence of columnar epithelial **cells of respiratory or intestinal type** is also indicative of a benign teratoma. Occasionally, unusual cells may be found in aspirates. Thus, Mulvany and Allan (1996) reported the presence of orderly clusters of **choroidal cells** in an aspirate from an **ependymal cyst** developing in a mature teratoma (Fig. 15-15). Canda et al (2001) reported the presence of **Curshmann's spirals** in fluid aspirated from a dermoid cyst, lined by bronchial epithelium. For further comments on Curshmann's spirals, see Chapters 10, 19, and 25.

P.505

Figure 15-14 Granulosa cell tumor. *A-C.* From the same case. *A.* Shows the original typical granulosa cell tumor removed at the age of 50. *B.* Five years later, the patient showed a remarkably high level of squamous cell maturation (high estrogen level) in her vaginal smear. Active search for recurrent granulosa cell tumor led to the discovery of a small metastatic nodule shown in *C.* *D.* Direct aspirate of a metastatic granulosa cell tumor. In this photograph at high magnification, the cells form a gland-like structure corresponding to a Call-Exner body. The large nuclei of the tumor show nuclear folds or creases. (*D* courtesy of Dr. Hormoz Ehya, Fox Chase Cancer Center, Philadelphia, PA.)

Figure 15-15 Teratoma of ovary showing clusters of choroid plexus cells in cyst aspirate (A). The corresponding tissue pattern in the resected teratomatous cyst is shown in *B.* (Photos courtesy of Dr. N. J. Mulvaney, Traralgon, Victoria, Australia.)

P.506

Sex Cord Tumor with Annular Tubules

Another benign ovarian tumor with cytologic implications is the rare ovarian sex cord tumor with annular tubules, observed in **Peutz-Jeghers syndrome**. The association of this tumor with **endocervical adenocarcinoma of the adenoma malignum type** has been noted (Young et al, 1982; Szyfelbein et al, 1984; see Chap. 12).

Hirschman et al (1998) described the cytologic features of this rare neoplasm in peritoneal washings in a most unusual case of ruptured tumor. The tumor was characterized by cellular tubular structures and absence of single tumor cells.

Malignant Germ Cell Tumors

Brenner Tumor

These tumors, composed of **nests of epithelial cells resembling the urothelium** (transitional epithelium) and **mucinous cysts**, may be benign or malignant. We have no experience with the cytologic patterns of these tumors. However, we observed cells suggestive of urothelial origin in an ovarian cyst, illustrated in Figure 15-6. Because the cyst was not excised, the exact derivation of these cells could not be established.

Figure 15-16 Embryonal carcinoma of ovary. *A,B.* The tumor in cervicovaginal smears was characterized by small cancer cells, singly and in papillary clusters, suggestive of an adenocarcinoma. *C.* Yolk sac tumor of ovary. High magnification to show hyaline body (arrow) adjacent to a cluster of tumor cells. (*C* courtesy of Dr. Hormoz Ehya, Fox Chase Cancer Center, Philadelphia, PA.)

Dysgerminoma

The tumors resemble **seminomas of testis** and are composed of **sheets of large cancer cells in a background rich in lymphocytes**. The cells of this tumor are approximately spherical and are provided with pale nuclei with single large nucleoli. The cytologic presentation in needle aspirates corresponds to that of seminoma in the testis. Hees et al (1991) emphasized the presence of a **striated “tigroid” background in the air-dried MGG-stained smears**, representing cell debris, a feature also characteristic of germ cell tumors of testis (see Chap. 33 and Fig. 33-19).

Malignant Teratoma

Malignant teratomas of the ovary are exceedingly rare. The malignant component may be made up of undifferentiated small malignant cells, resembling neuroblastoma. In rare cases, a **carcinoid** or a **carcinoma**, most often of **squamous type**, rarely of **thyroid type**, may arise in a dermoid cyst. Baker et al (2001) reported the presence of **mucin-producing carcinoids** in teratomas. There is no record of such cases in the cytologic literature.

Embryonal Carcinoma

We observed one instance of the highly malignant **embryonal adenocarcinoma** in cervicovaginal smears from a 15-year-old girl. The tumor shed small malignant cells with prominent nucleoli, either singly or in papillary clusters. The

P.507

smear pattern was suggestive of an adenocarcinoma (Fig. 15-16A,B). Other rare tumors are discussed in Chapter 17.

Yolk Sac Tumor (Endodermal Sinus Tumor)

This is an uncommon, highly malignant tumor of ovaries occurring in children and young people. The tumors may be primary in the **ovary**, **testis**, or the **sacroccocygeal region**. The tumor is histologically characterized by a loose network of cells wherein one finds solid nests of cells and the so-called **Schiller-Duval bodies**, papillary structures lined by columnar cells, centered around a fibrovascular core containing a single vessel (Yang, 2000). **Eosinophilic, periodic acid-Schiff (PAS) positive, spherical hyaline bodies** are commonly found in the cytoplasm of the tumor cells (Fig. 15-16C). Although the tumors produce **α -fetoprotein**, the hyaline bodies are not immunoreactive with the specific antigen because they represent electron-dense granules of not further specified nature. Because, in most cases, the tumors are advanced at the time of diagnosis, they are recognized in ascitic fluid or in aspirates of metastases. **Clusters of epithelial cells containing the characteristic hyaline cytoplasmic inclusions** (which may also appear as isolated hyaline structures) allow the precise diagnosis of these tumors (Morimoto et al, 1981; Kapila et al, 1983, Roncalli et al, 1988; Domínguez-Franjo et al, 1993; Mizrak and Elkinici, 1995).

DNA Analysis of Ovarian Tumors

It has been shown by several observers that common ovarian cancers have a better prognosis if their DNA content measured by flow cytometry is within the diploid range (Atkin, 1984; Friedlander et al, 1984; Iverson and Laerum, 1985; Kallioniemi et al, 1988). Greenebaum et al (1994) found the technique useful in separating benign (diploid) from suspicious or malignant (nondiploid) aspirates from ovarian cysts. For further comments, see Chapter 47.

DIAGNOSIS OF OCCULT OVARIAN CARCINOMA

The high frequency and poor outcome of ovarian carcinoma, with spread beyond the ovary at the time of diagnosis, has led to numerous efforts at early detection of these tumors. It is now known from the results of prophylactic salpingo-oophorectomy in high risk women with mutations of BRCA1 and 2 that small ovarian tumors and other possibly precancerous epithelial changes may be observed (Bell and Scully, 1994; Salazar et al, 1996; Kauff et al, 2002). Finding such tiny tumors before further spread has been a major challenge over many years.

Routine Cervicovaginal Smears

The finding of cancer cells suggestive of an adenocarcinoma in cervicovaginal smears or in an endocervical or endometrial aspiration in an **asymptomatic patient** presents a difficult clinical dilemma. A thorough clinical examination, an ultrasound examination, a CT scan, a peritoneoscopy, or even an exploratory laparotomy may reveal a clinically occult ovarian (see Fig. 15-9) or a tubal carcinoma (see below). Occasionally, this may lead to the diagnosis of a **carcinoma still confined to the ovary**, hence offering a good chance for a cure. In my experience, however, most ovarian carcinomas diagnosed by cervicovaginal cytology are usually advanced and have formed metastases, usually to the omentum or the lower genital tract. Thus, routine cytologic preparation offers limited hope for the diagnosis of ovarian cancer in early stages. Other tumors that must be considered in the differential diagnosis are endometrial carcinoma and metastatic carcinoma from a distant site.

Detection of Early Ovarian Carcinoma by Special Techniques

Because the results of treatment of fully developed ovarian carcinoma are not satisfactory, in

1962, Graham et al suggested the use of **cul-de-sac aspiration via the vaginal route (culdocentesis)** for the diagnosis of early, clinically occult ovarian cancers. The original study was based on examination of 576 volunteer patients and gave eight positive results. Seven patients were explored and the ovaries examined: one had metastatic breast cancer, one had no demonstrable lesion, four had papillary ovarian lesions of "borderline malignancy," and one had a "probable borderline lesion." Subsequently (1964 and 1967), these authors reported on an additional eight ovarian lesions showing abnormalities of surface epithelium. Because of current interest in early carcinomas of the ovary, especially "**early ovarian intraepithelial neoplasia or dysplasia**" of the surface epithelium (Plaxe et al, 1990), histologic sections of the original ovaries reported by Graham et al (1964), were reexamined by Werness and Eltabbakh (2000). On re-examination, the eight ovaries were considered to be within normal limits. Long-term follow-up of 7 of the 8 patients was noncontributory and none of them had any evidence of ovarian cancer. The experience with this method of ovarian cancer detection since the publication of the 1964 and 1967 reports by Graham et al has remained inconclusive. Several published papers (McGowan et al, 1966; Grillo et al, 1966; Zervakis et al, 1969; Funkhouser et al, 1975) gave equivocal results. Keettel et al (1974) gave a pessimistic appraisal of the value of the procedure.

Although early carcinomas may be occasionally observed on the surface of the ovaries (Bell and Scully, 1994), most ovarian cancers develop within ovarian cysts that remain intact, possibly for long periods of time. Therefore, there is significant doubt that the cul-de-sac aspiration will indeed significantly contribute to the salvage of lives.

As reported by Greenebaum et al (1992, 1996), it is occasionally possible to discover an early ovarian cancer while harvesting ova in in vitro fertilization patients. This event is exceedingly rare. The procedure has been described in the earlier part of this chapter.

Transvaginal sonographic screening (TVS) has been shown to be capable of uncovering ovarian lesions, although in some early studies (Goswamy et al, 1983), many false

P.508

alarms were generated because of enlarged benign ovaries. Three per cent of screened women without evidence of malignant disease required laparoscopy or laparotomy. Recently, Van Nagell et al (2000) reported on the efficacy of TVS in 14,469 women, ages 50 or older (or younger women with family history of ovarian cancer), conducted from 1987 to 1999. The principal criteria for laparoscopy or exploratory laparotomy were: large ovarian volume or papillary or complex tissue projections in cysts, verified on a repeat examination 4 to 6 weeks after the original sonogram. In 180 women explored 17 ovarian cancers were detected, most in stages I and II of disease. In the remaining 163 women, numerous other benign ovarian lesions were observed. Eight additional women subsequently developed ovarian cancer in the absence of sonographic abnormalities. The conclusions of this paper suggested that **TVS in fortuitous cases leads to the detection of occult ovarian cancer with a low positive predictive value of only 9.4% but a high negative predictive value of 99.07%**. In other words, a negative TVS offers a high degree of assurance that the risk of ovarian cancer in a given patient is low. Unfortunately, the system fails in the detection of ovarian cancer in ovaries with normal volume. **The procedure may be of particular value in women who have germ-line mutations of breast cancer genes (BRCA1 and 2)** (Rubin et al, 1996).

There is no evidence that serologic studies, particularly measuring the serum levels of antibodies with a high degree of specificity for ovarian cancer, such as CA 125 or OV 632, are applicable as a screening test for ovarian cancer, although the determinations may be of value

in recurrent cancer (Niloff et al, 1968; Koelma et al, 1988; Malkasian et al, 1988).

Proteomics

Most recently, protein patterns in blood plasma, characteristic of ovarian cancer, generated by **proteomic spectra**, obtained with mass spectroscopy, have been reported as a promising approach to early detection of ovarian cancer (Bicsel et al, 2001; Petricoin et al, 2002; Rai et al, 2002). Algorithms generated by proteomics have been effectively applied to the identification of patients with ovarian cancer with sensitivity of 100% and specificity of 95% (Petricoin et al, 2002). Excellent results were also claimed by combining proteomics with other markers, such as CA 125 (Rai et al, 2002). The value of the proteomics still needs testing on a large population.

FALLOPIAN TUBE

HISTOLOGIC RECALL

The epithelium of the fallopian tubes is composed of three types of cells. The dominant cell type is the **columnar ciliated cells** that closely resemble in size and configuration similar cells observed in the lining of the endocervical canal. The second cell type is the **secretory cells** that are interspersed among ciliated cells which they resemble, except for clear cytoplasm and the absence of cilia. The luminal aspect of the secretory cells often shows "snouts" of secretions on their surface. The third cell types are the least frequent **intercalary or peg cells**, narrow cells with thin, dark-staining nucleus. The epithelium is separated from the two muscular layers by a thin lamina propria of connective tissue.

Normal tubal epithelial cells are virtually never seen in normal cervicovaginal smears, except as the so-called tubal metaplasia, discussed in Chapter 10.

BENIGN DISORDERS

The fallopian tubes may be affected by a variety of benign disorders, some of which may have cytologic implications.

Inflammatory disorders, such as **tuberculosis** and **chlamydia** infection may cause tubal obstruction and dilatation (**hydrosalpinx**) that may lead to **tubal pregnancy**. These conditions may be sometimes mistaken for tumors. Seidman et al (2002) observed that **chronic salpingitis** with formation of psammoma bodies (named here **salpingoliths**; see Fig. 15-12B) may be related to serous carcinoma of ovary and peritoneal implants.

A variety of **cysts**, ranging from **simple serous paraovarian cysts** to **endometriosis** and **endosalpingiosis**, may be observed on the serosal surface of the tubes. Some of these cysts, if of significant sizes, may be aspirated. The cytologic presentation of these cysts is identical to ovarian cysts, discussed above. More importantly, perhaps, these cystic structures may be sometimes recognized in peritoneal washings, discussed below.

CARCINOMA OF FALLOPIAN TUBES

Histology and Clinical Features

Carcinoma of the fallopian tube resembles ovarian and endometrial adenocarcinomas and may occur in a **variety of histologic patterns, some papillary, some solid**. A stage of **carcinoma in situ** has been recognized.

Most lesions are usually discovered too late for effective treatment, although they often produce

vaginal spotting or bleeding for which no obvious cause can be found (review in Nordin, 1994). Sedlis (1961), upon review of the literature, pointed out that those patients who had the benefit of routine cytologic examination had a surprisingly high percentage (40%) of positive diagnoses. Fidler and Lock (1954) go so far as to say: "The triad of vaginal spotting or hemorrhage, lower abdominal pain and pelvic mass, when accompanied by positive cytology and negative cervical and endometrial biopsy is practically diagnostic of tubal carcinoma." This is an extreme view, since many cancers of other origins may have a similar clinical and laboratory presentation. Heselmeyer et al (1998) observed high levels of genomic instability in 12 tubal carcinomas

P.509

studied by comparative genomic hybridization. The tumors were free of human papillomavirus but most were strongly reactive with p53 antibody. These authors attributed the poor prognosis of these tumors to their genetic and molecular features.

In a recent communication, Agoff et al (2002) reported high frequency of tubal carcinoma in women with **proven or suspected BRCA1 or 2 mutations**. In four of the seven cases reported, the **tumors were occult** and two of them were discovered in pelvic washings in patients undergoing **prophylactic salpingo-oophorectomy**.

Tubal Carcinoma in Cervicovaginal Smears and Endometrial Samples

Tubal carcinoma may be recognized in **cervicovaginal smears** and in **direct endometrial samples**. The **cytologic presentation of tubal carcinoma cannot be distinguished from that of an ovarian adenocarcinoma**. **Large malignant cells**, sometimes with vacuolated cytoplasm, hyperchromatic large nuclei, and **prominent nucleoli**, are found in cervicovaginal smears singly and in papillary clusters (Figs. 15-17 and 15-18). If the lesion is small, **the problems of localization of tubal carcinoma** may prove to be difficult, not only clinically or at the time of surgery, but even at the time of examination of the specimen by the pathologist. This sequence of events is illustrated in Figure 15-19. As in cases of occult carcinomas of the ovary, discussed above, if the results of the clinical and ultrasound examination of the vagina, cervix, and endometrium are normal, a laparotomy may be needed to clarify the origin of malignant cells. A case of a **tubal carcinoma in situ**, diagnosed in an endometrial sample, was reported by Luzzatto et al (1996). The smear pattern in this case was again identical to an ovarian carcinoma because of the presence of **psammoma bodies** and cells of adenocarcinoma.

Figure 15-17 Carcinoma of a fallopian tube discovered on cervicovaginal smear. *A.* A cervicovaginal smear with a single cluster of cells suggestive of an adenocarcinoma. The tumor was clinically occult. *B,C.* Low and higher power views of the fallopian tube showing a poorly differentiated adenocarcinoma.

Excellent results of cytologic examination in 128 patients with tubal cancer were reported by Takashina and Kudo (1985) on the basis of **cervicovaginal smears** (positive in 38% of 58 patients) and **direct endometrial samples** (positive in 80% of 15 patients). Hirai et al (1987) and Takeshima et al (1997) also reported good diagnostic results by **endometrial aspiration smears** in 6 of 20 patients with tubal cancer. We also observed a case of occult tubal carcinoma diagnosed in an endometrial aspiration from an asymptomatic patient during the search for occult endometrial cancer (see Fig. 15-18).

Rare tumors of the fallopian tube include **mesodermal mixed tumors** (Kinoshita et al, 1989), a **carcinosarcoma** (Axelrod et al, 1989), and a **glassy cell carcinoma** (Herbold et al, 1988).

For further discussion of rare tumors see Chapter 17.

Figure 15-18 Adenocarcinoma of fallopian tube detected on endometrial aspiration smear. *A.* A large papillary cluster of cancer cells with very large nuclei and prominent nucleoli observed in an endometrial aspirated sample. This appearance is identical to that observed in serous carcinomas of ovary. *B,C.* Histologic appearance of fallopian tube. *B.* Adenocarcinoma composed of very large cells. *C.* An area of carcinoma in situ at the periphery of invasive tumor shown in *B.*

Figure 15-19 Adenocarcinoma of fallopian tube. The tumor was very difficult to localize in the surgical specimen. *A.* A papillary cluster of malignant cells in cervicovaginal smear. *B.* The gross appearance of the uterus and the fallopian tube. The fallopian tube was folded but not thickened. *C.* Adenocarcinoma of fallopian tube was identified and diagnosed only after numerous cross sections of the tube were examined.

Peritoneal Washings or Lavage in Cancers of the Female Genital Tract

Cytologic sampling of **fluid from the peritoneal cavity** or, more specifically, from the pelvic cul-de-sac (pouch of Douglas), at the time of surgery was first proposed for ovarian tumors by Keettel and Pixley (1958). **The purpose of the procedure was to improve the staging of these tumors.** In 1958, Keettel and Pixley published preliminary results indicating that this procedure may provide **evidence of spread of ovarian cancer in the absence of visible lesions.** In 1986, this concept was incorporated into the official **staging of ovarian cancer** by the International Federation of Gynecology and Obstetrics (FIGO), shown in Table 15-2.

This staging system attributes an important diagnostic role to the cytologic examination of ascitic and peritoneal fluids: the presence of cancer cells modifies the staging of ovarian tumors from stages Ia or Ib to Ic and from IIa and IIb to IIc. The higher staging calls for a different approach to treatment with the recognition that surgery alone is not likely to be curative of the disease. In current practice the aspiration of pelvic fluid is often supplemented by washings of the cul-de-sac, the fluids being submitted for cytologic examination. Additional data on cytology of ascitic and pleural fluids in ovarian cancer are provided in Chapter 26.

The principal applications of pelvic peritoneal lavage are:

- **Staging of ovarian, and, somewhat less commonly, other gynecologic cancers**
- **Securing evidence of persisting or recurring cancer during the second-look surgical procedures**
- **Occasional discovery of occult cancer during exploratory laparotomies or laparoscopies for benign disease**
- **Incidental discovery of metastatic cancer from non-gynecologic sites**

SECURING AND PROCESSING THE SPECIMEN

McGowen et al (1966) advocated the **aspiration of accumulated peritoneal fluid** as the first step upon surgical entry into the abdominal cavity, using a laryngeal cannula with a blunted end, attached to a syringe. A **washing or lavage** of the pelvic peritoneum can be performed using small amounts of normal saline solution or similar fluid that can be repeatedly instilled and reaspirated. If the fluid cannot be processed by the laboratory without delay, the addition of a fixative is recommended (see Chap. 44). **Culdocentesis,**

P.515

an aspiration of pelvic peritoneal fluid across the vaginal wall, may be used for the same purposes. Aspirations may also be performed by skilled operators at the time of a **laparoscopy.**

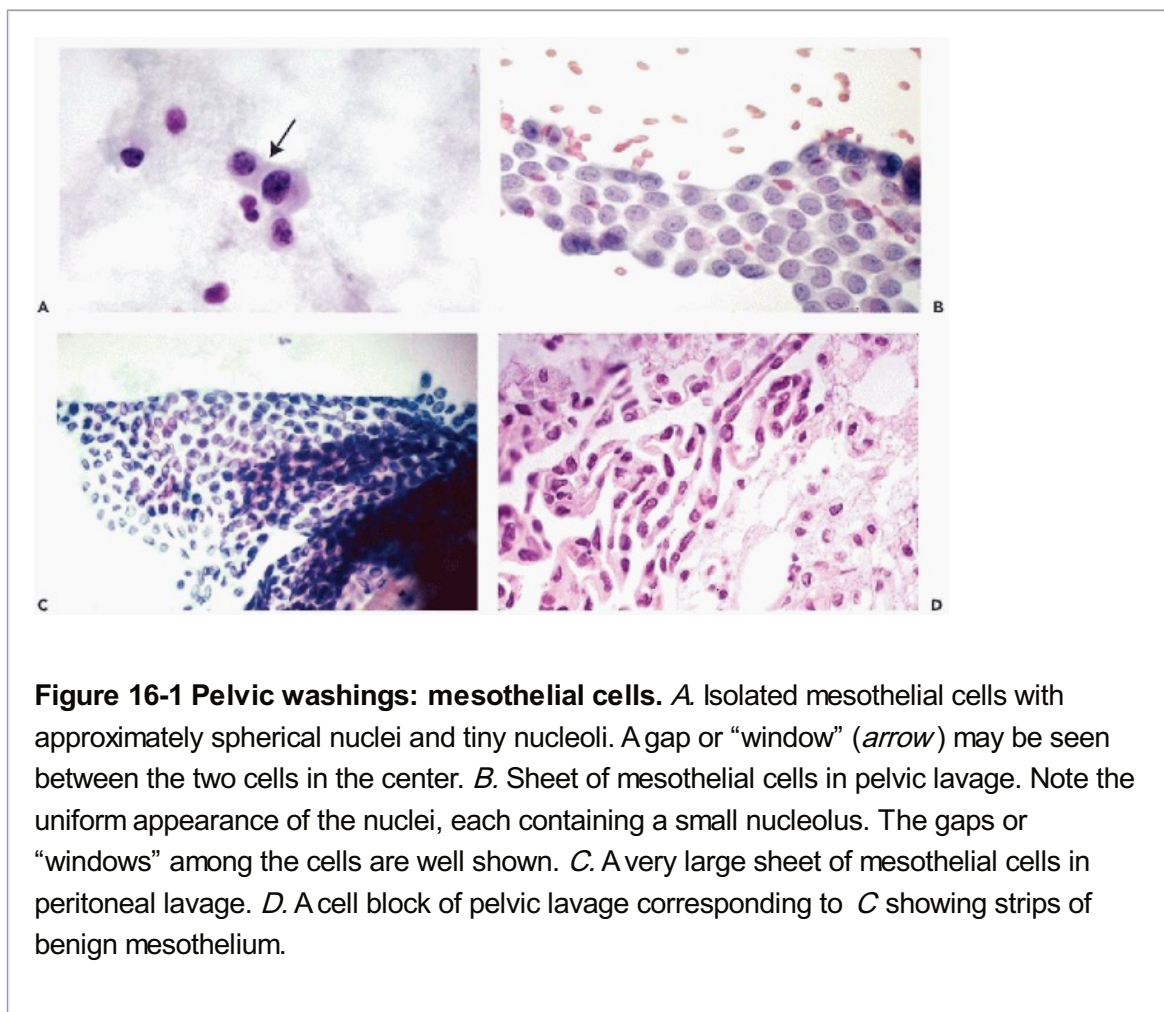

Luesley et al (1990) advocated the use of **direct scrapings or brushings** of the peritoneal surfaces as superior to lavage specimens. We do not have any experience with this technique.

The processing of peritoneal aspirates or lavage samples calls for centrifugation of the specimen and preparation of smears or cytopsin preparations, as described in Chapter 44. In our experience the use of **cell blocks** supplementing smears is often diagnostically helpful. Poorly preserved specimens of peritoneal fluid, submitted without fixative after a substantial delay, or unfixed smears prepared by inexperienced personnel may be difficult to interpret. In this type of material, overstained and poorly preserved mesothelial cells may be mistaken for cancer cells. The risk of a falsepositive diagnosis in such cases is substantial.

CYTOLOGY OF PERITONEAL LAVAGE

Benign Cells and Conditions

The principal benign cellular components of peritoneal fluids are mesothelial cells, macrophages, leukocytes, and epithelial cells or cell fragments derived from the peritoneal lining and various benign cysts and other structures. The fluids may also contain “**collagen balls**,” described by Wojcik and Naylor (1992), calcified debris and, occasionally, psammoma bodies.

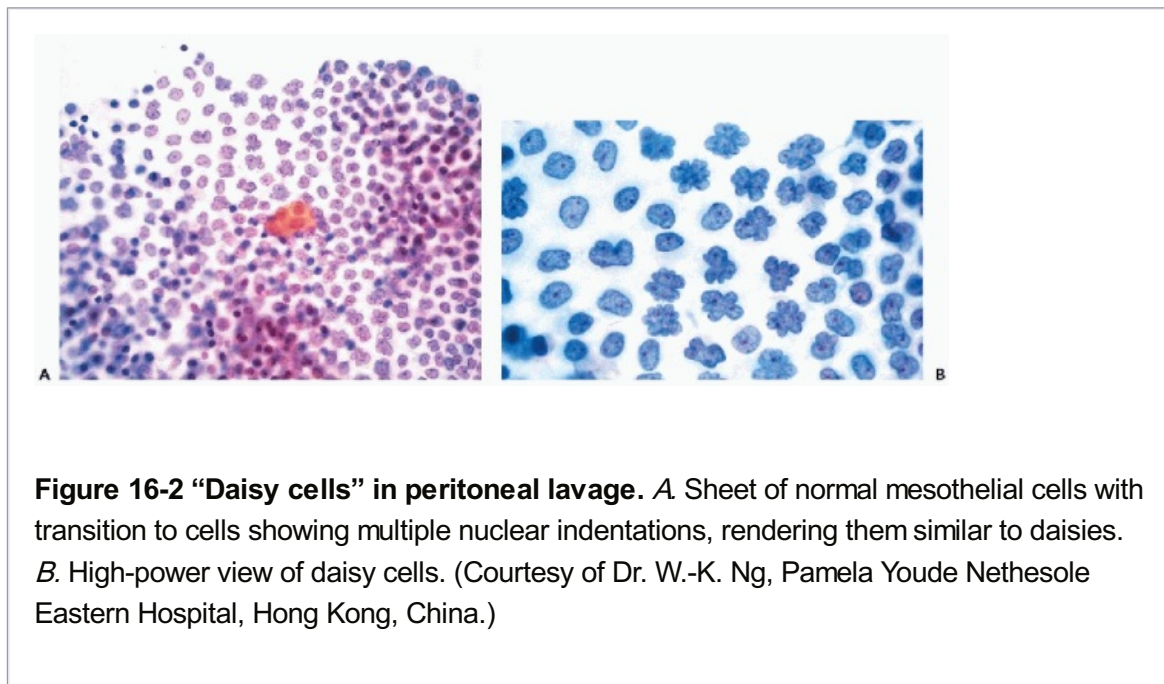

Mesothelial Cells

The principal characteristics of mesothelial cells are described in great detail in Chapter 25. In the context of the peritoneal fluid, the mesothelial cells are fairly easy to recognize when well

preserved: the cells are of medium size, comparable to small parabasal squamous cells, and have a generally basophilic, delicate cytoplasm, wherein the outer zone is often lighter than the inner, perinuclear zone (Fig. 16-1A). However, depending on the technique used in processing the material and speed of fixation, the mesothelial cells may **vary in size** and staining properties among specimens. When in **flat sheets**, the mesothelial cells are often separated from each other by narrow clear gaps or “windows” (Fig. 16-1B,C). Sometimes, **long strips of mesothelial cells**, forcibly removed from their setting, may be observed in cell blocks (Fig. 16-1D). The cells have **central, round, but sometimes slightly indented nuclei**, occasionally containing visible **small nucleoli** (Fig. 16-1A,B). The presence of nucleoli may be troublesome to an inexperienced observer, who may confuse such cells with cancer cells; the fairly monotonous size of the mesothelial cells and their nuclei should prevent the erroneous diagnosis. Through the courtesy of Dr. Wai-Kuen Ng of the Pamela Youde Nethersole Eastern Hospital in Hong Kong, I was privileged to see a very unusual variant of mesothelial cells in peritoneal washings characterized by **lobulated nucleus**. The term “**daisy cells**” has been appended to these cells, which were apparently observed before in peritoneal washings. A transition between normal mesothelial cells and “**daisy cells**” is shown in Figure 16-2. Such cells have not been observed by us in any other fluid and, hence, appear to be a unique feature of peritoneal mesothelial cells.

P.516

Figure 16-3 Mesothelial and epithelial cells in peritoneal lavage. *A.* A papillary cluster of benign mesothelial cells, mimicking adenocarcinoma. Note the monotonous makeup of the benign cluster. *B.* A sheet of mesothelial cells showing gaps or “windows” between the cells and the presence of small nucleoli. *C,D.* Sheets of benign epithelial cells in cul-de-sac lavage. In *C*, the cells are somewhat similar to mesothelial cells, except for angulated cytoplasm. *D.* Small papillary cluster of benign epithelial cells, some showing cytoplasmic vacuolization. The nuclei are small, each containing a tiny nucleolus.

P.517

It is not uncommon, however, to see mesothelial cells in large, densely packed sheets wherein the individual cells are difficult to study (Fig. 16-3A,B). As a rule, **the diagnosis of cancer should not be made unless the characteristics of cells and their nuclei can be studied in detail**; the thick sheets or dense clusters of mesothelial cells are no exception to this rule.

Benign Epithelial Cells

Benign epithelial cells of various types may be observed in peritoneal washings, especially after a vigorous irrigation. These may represent a variety of structures, from ruptured **benign inclusion cysts**, commonly found on the surfaces of tubes and ovaries, foci of **endosalpingiosis** and **endometriosis**, or benign **ciliated tubal epithelium**. The cells may be of **cuboidal or columnar configuration** (Figs. 16-3C,D and 16-4A,B) and may appear singly or may form sheets or even papillary clusters, composed of small cuboidal or columnar cells with **inconspicuous nuclei and nucleoli**. Some of the cells **may be ciliated**. Detached **ciliated tufts of tubal origin** may also be observed (Poropatich and Ehya, 1986). Sidawy et al (1987) correlated the presence of the ciliated tufts with stages of menstrual cycle and observed them only in the secretory stage (Fig. 16-4C,D).

Figure 16-4 Ciliated cells and ciliated tufts in pelvic lavage. *A.* Large sheets of ciliated columnar cells representing epithelial lining of the fallopian tubes. *B.* High-power view of a cluster similar to that shown in *A* showing cilia on the surface of the cells. *C,D.* Isolated ciliated tufts in pelvic lavage. The details of the tufts are well shown at oil immersion magnification in *D*. (*C,D* photographs courtesy Dr. Mary Sidawy, George Washington University, Washington DC.)

Leukocytes and Macrophages

In “**first look**” specimens and in the absence of cancer, the leukocytes are usually few in number, **except in the presence of an inflammatory process**. In the latter condition, macrophages accompanied by leukocytes of various types, fibrin and necrotic material may be observed. Cancerous processes may also be accompanied by an inflammatory reaction. In “**second look**” procedures, a marked inflammatory reaction is often present (see below).

Macrophages may vary in size: most are mononucleated

P.518

cells, **comparable in size to mesothelial cells**, but having **finely vacuolated cytoplasm** and **peripheral, spherical or kidney-shaped nuclei** of similar size. **Large cytoplasmic vacuoles** may occur, pushing the nucleus to the periphery. Evidence of **phagocytosis** in the form of ingested particles of pigment, such as hemosiderin, helps in the identification of these cells, although sometimes cancer cells are also capable of phagocytosis. Macrophages may also form large, either **mono- or multinucleated giant cells**; the latter are commonly observed in patients with chronic inflammatory processes or as a reaction to foreign bodies, such as powder, usually observed after a surgical intervention. Macrophages are more common in “second look” procedures.

Collagen Balls

Under this term, Wojcik and Naylor (1992) analyzed the frequency and origin of peculiar **homogenous structures, lined by a single layer of cuboidal cells** that may be observed in about 5% of pelvic fluids and lavage specimens (Fig. 16-5A,B). In one such case, the structures

could be traced to small collagenous excrescences on the surface of an ovary, hence, the conclusion that the small cuboidal cells represent ovarian epithelium. We have observed the collagen balls in **benign and malignant peritoneal lavage specimens** and, therefore, they have no diagnostic significance.

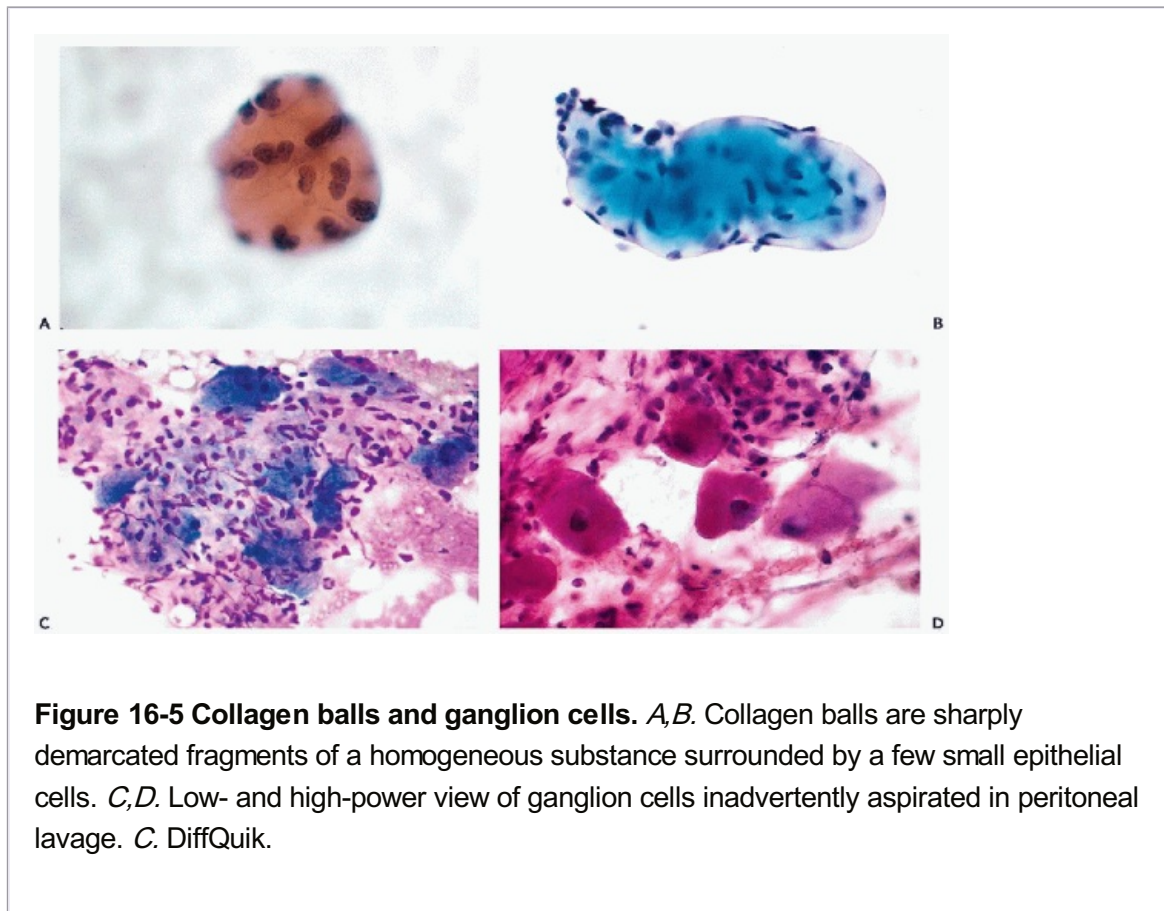

Figure 16-5 Collagen balls and ganglion cells. *A,B.* Collagen balls are sharply demarcated fragments of a homogeneous substance surrounded by a few small epithelial cells. *C,D.* Low- and high-power view of ganglion cells inadvertently aspirated in peritoneal lavage. *C.* DiffQuik.

Foreign, Plant, and Ganglion Cells

During cul-de-sac aspirations performed with a needle-syringe system, a loop of bowel may be inadvertently penetrated. **Epithelial cells of intestinal origin or** bowel contents in the form of **plant cells** may be observed. The **enteric cells** are usually columnar and may occur in large clusters. The **plant cells** may be identified by a thick, transparent cellulose wall and fine, refractile cytoplasmic granules (see Chapters 8 and 19). Rare findings in aspirates include **large ganglion cells**, with abundant granular cytoplasm and peripheral nuclei, inadvertently removed from presacral ganglia (Fig. 16-5C,D).

Endometriosis

In abdominal endometriosis two types of cells may be seen side by side: **small cuboidal or columnar epithelial cells, usually in small sheets**, and, very rarely, very small, spindly stromal cells; these cells are usually accompanied by **hemosiderin-laden macrophages**. An iron stain may be occasionally helpful in establishing the diagnosis (see Chap. 34). Stowell et al (1997) examined the accuracy of cytologic examination of peritoneal fluids in the diagnosis of endometriosis and concluded that the identification of epithelial cells of endometrial origin is difficult but that the presence

of hemosiderin-laden macrophages should alert the pathologist to the possibility of this

disorder.

Endosalpingiosis

In endosalpingiosis the fluids are characterized by the presence of **calcified debris and psammoma bodies that can be numerous**, and are sometimes surrounded by inconspicuous, small, benign epithelial cells (Fig. 16-6; see also Fig. 15-7). Psammoma bodies may also occur within fragments of glandular structures or surrounded by inflammatory exudate and cell debris (Fig. 16-6C).

In incidental biopsies, **small cystic structures**, lined by cuboidal, occasionally ciliated, epithelial cells and containing calcified debris or psammoma bodies, may be observed on the surface of the fallopian tubes, the ovaries, and elsewhere in the peritoneum (see Fig. 15-7). For a discussion on the possible relationship of endosalpingiosis to psammocarcinoma, see Chapter 15.

The presence of psammoma bodies in peritoneal lavage may be perplexing, particularly in the presence of ovarian abnormalities that may be unrelated to the cytologic findings (Sidawy and Silverberg, 1987). In general, **psammoma bodies or calcified debris observed in peritoneal washings, do not have the same diagnostic significance as in vaginal and cervical material** (see Chap. 15) or in effusions (see Chap. 26) **and, unless accompanied by cancer cells, should be interpreted with great caution**. Focal calcium deposits, not uncommon in the peritoneum, may be dislodged by vigorous lavage and may mimic psammoma bodies.

Figure 16-6 Endosalpingiosis in peritoneal lavage. *A*. A cluster of psammoma bodies surrounded by a layer of small epithelial cells. In *B*, the psammoma bodies are superimposed upon each other. *C*. Psammoma bodies surrounded and accompanied by sheets of epithelial cells. *D*. Isolated, calcified psammoma bodies from a case of endosalpingiosis. (*A,B* case courtesy of Dr. F. Bonetti, Verona, Italy.)

Ravinsky (1986), Zuna and Mitchell (1988), and Zuna et al (1989) presented comprehensive reviews of their experiences with peritoneal lavage. In the absence of cancer, **benign ovarian cysts and endometriosis** presented significant diagnostic dilemmas. Zuna and Mitchell (1988) recorded diagnostic difficulties in 12% of 149 benign peritoneal washings. In my experience, besides atypical mesothelial cells and, rarely, atypical epithelial cells, **endosalpingiosis is the most common source of diagnostic difficulty**, particularly if there is an association of psammoma bodies with sheets of epithelial cells. Selvaggi (2003) recommended the use of cell blocks and immunostains in difficult cases. Sams et al (1990) reported an exceedingly rare case of **ectopic pancreas** that shed cells mistaken for cancer cells.

P.520

PERITONEAL LAVAGE IN OVARIAN CANCER

“First Look”

The most common indication for peritoneal washings is **staging or upstaging of ovarian carcinomas**. Usually, but not always, cancer cells stand out as a different population of cells, easily separated from benign cells.

Serous Adenocarcinomas

Malignant cells most often observed in peritoneal washings are derived from fully developed carcinomas of the serous type. Such cells occur **singly** and in **structured, approximately spherical clusters**. The cytoplasm is usually delicate and finely vacuolated. The dominant feature of these cells is **nuclear abnormalities, such as nuclear enlargement, irregular nuclear configuration and the presence of prominent, often multiple nucleoli** (Fig. 16-7). Such malignant cells may be occasionally confused with benign mesothelial or epithelial cells which, however, are usually much smaller. **Papillary clusters of cancer cells with nuclear hyperchromasia**, of the type commonly observed in cells of ovarian cancer in cervicovaginal material (see above), **are less common but may occur** (Fig. 16-8A,B). **A central core of connective tissue may be sometimes observed in the papillary clusters**, a feature that is usually better seen in cell block preparations (Fig. 16-7B). **Psammoma bodies** may occur, but, unless accompanied by cancer cells, have limited diagnostic value, as discussed above (Fig. 16-7D).

Figure 16-7 Papillary carcinoma of ovary in peritoneal wash. *A,B.* From the same case showing a large papillary cluster of malignant cells and dispersed malignant cells at the periphery of the cluster. *B.* Cell block showing the glandular structure of the tumor. *C.* Another example of serous carcinoma of ovary in cul-de-sac washings. The large cancer cells form a papillary cluster. Note the large nuclei and nucleoli. *D.* Psammoma body in a case of serous carcinoma in pelvic lavage. Note that the psammoma body is surrounded by large cancer cells with hyperchromatic nuclei.

Serous carcinomas of the peritoneum, some of which may be **occult**, shed large cohesive clusters of cancer cells (see Fig. 16-9C,D). For further discussion and examples of this entity, see Chapter 26.

The **low-grade (borderline) serous ovarian tumors** shed **atypical but not clearly cancerous epithelial cells, usually forming cohesive clusters** (see Fig. 15-11). The nuclear abnormalities are usually more modest than in high-grade carcinomas, specifically the **nucleoli are usually small and inconspicuous**, but in some cases the cells are similar to those of a well-differentiated serous carcinoma. Gurley et al (1994) compared by image analysis the nuclear features of borderline serous tumors with low-grade carcinomas. The borderline tumors displayed less nuclear pleomorphism and were diploid, whereas the carcinomas were aneuploid. This paper pointed out the difficulties of precise cytologic classification of the spectrum of well-differentiated

P.521

serous tumors in peritoneal lavage specimens, a point also stressed by Mulvany (1996).

Figure 16-8 Ovarian and peritoneal serous carcinomas in pelvic lavage. *A.* A large cluster of cancer cells in pelvic lavage corresponding to the tumor shown in *B.* *C,D.* Large compact papillary clusters of cancer cells in a case of primary peritoneal serous carcinoma in pelvic lavage.

Mucinous Carcinomas and Borderline Tumors

In the absence of obvious spread to the peritoneum, resulting in **pseudomyxoma peritonei** and accumulation of ascitic fluid (discussed in Chapter 26), these tumors are **practically never observed** in peritoneal lavage specimens. However, **late recurrences** of the tumors may occur and may be diagnosed in cytologic preparations. In such preparations, the malignant nature of the cells is unmistakable (see Fig. 15-12).

Endometrioid Carcinoma

The cytologic presentation of endometrioid ovarian carcinoma in peritoneal lavage **is identical to that of metastatic endometrial cancer**, discussed below.

Other ovarian tumor types may occasionally be encountered, and their identification depends on the make-up of the primary tumor. Ravinsky (1986) reported examples of **clear cell carcinoma of the ovary** (also observed by Mulvany, 1996), **malignant granulosa cell tumor** and a **malignant teratoma**.

Clinical Significance

Peritoneal samples showing evidence of **serous or endometrioid carcinoma** indicate either the **presence of the tumor on the surface of the ovary**, or as a **metastatic deposit on the peritoneal surfaces**. They may also indicate the existence of a **primary peritoneal tumor, a mimicker of serous carcinoma**. In Mulvany's experience (1996), approximately one half of 14 patients with serous carcinomas were **upgraded as a consequence of peritoneal lavage containing cancer cells**. However, this study was limited to lavages showing definite cancer cells and the author did not attempt to present the rate of false-negative lavages. In the experience of Mathew and Erozan (1997), upstaging of gynecologic cancer occurred in 12, or

3%, of 125 cancer cases.

In **borderline serous tumors**, the cytologic abnormalities in lavage specimens may indicate the presence of **peritoneal deposits that may be either invasive or noninvasive and this important prognostic difference cannot be determined in peritoneal lavage**. Cheng et al (1998) reviewed their experience with 90 patients with ovarian tumors of low malignant potential. In one third of these patients, cancer cells were observed in peritoneal lavage specimens, most often with tumors of serous type, less often with mucinous tumors. Positive cytology correlated well with the presence of peritoneal implants, regardless whether or not the implants were invasive. Gammon et al (1998) observed positive peritoneal washing results in four patients below the age of 25.

For further descriptive comments on ovarian cancer cells in fluids, see Chapter 26.

P.522

“Second Look”

Second-look procedures are performed in patients previously treated by surgery, radiotherapy, chemotherapy, or a combination thereof, to determine the presence of residual or recurrent ovarian cancers. **The purpose of the second-look procedure is to ascertain whether the disease has been eradicated, and hence whether or not the patient requires additional treatment.** At the time of the second-look procedure, it is customary to obtain multiple biopsies of any area of the peritoneum or mesentery that shows thickening or other changes suggestive of residual disease; the examination of the peritoneal fluid or washings is a part of this procedure.

If the cytologic examination of the peritoneal fluid in untreated patients is fraught with pitfalls, the difficulties are often increased in patients previously treated. The therapeutic regimens affect not only the residual cancer but also many of the benign structures, notably the mesothelium. Occasionally, acute or chronic inflammatory processes intervene, rendering the diagnostic process even more difficult.

To be sure, in some patients who failed to respond to therapy, **easily recognizable cancer cells may be observed** (Fig. 16-9A-C). Sagae et al (1988) suggested that in such cases quantitation of the malignant cells (comparing the initial sampling with the second sampling) may be of prognostic value.

Figure 16-9 Serous carcinoma of ovary on “second look” pelvic lavage. *A,B.* Large cancer cells with hyperchromatic nuclei and large nucleoli corresponding to metastatic ovarian carcinoma in the jejunum shown in *C*. *D.* A fairly disorderly cluster of overstained mesothelial cells mimicking cells of serous carcinoma.

In most patients, however, the **dominant cell population is benign mesothelial cells, showing effects of therapy.** Such cells may be **enlarged** and have a **thickened, often eosinophilic cytoplasm and proportionately enlarged nuclei, wherein prominent chromocenters or nucleoli may be present** (Fig. 16-9D). It is quite easy to confuse such cells with epithelial cancer cells. Sagae et al (1988) observed that mesothelial cell changes are more significant with the intraperitoneal use of alpha-2 interferon than with cisplatin. In my experience, however, any intensive radiotherapy or chemotherapeutic regimen can cause mesothelial cell abnormalities.

Another source of difficulty is the presence of **multinucleated and sometimes atypical macrophages.** With vigorous lavage, the **epithelial lining cells of ruptured benign peritoneal inclusion cysts** may contribute to the difficulty, especially if showing radiation changes (see Chapter 18).

Results

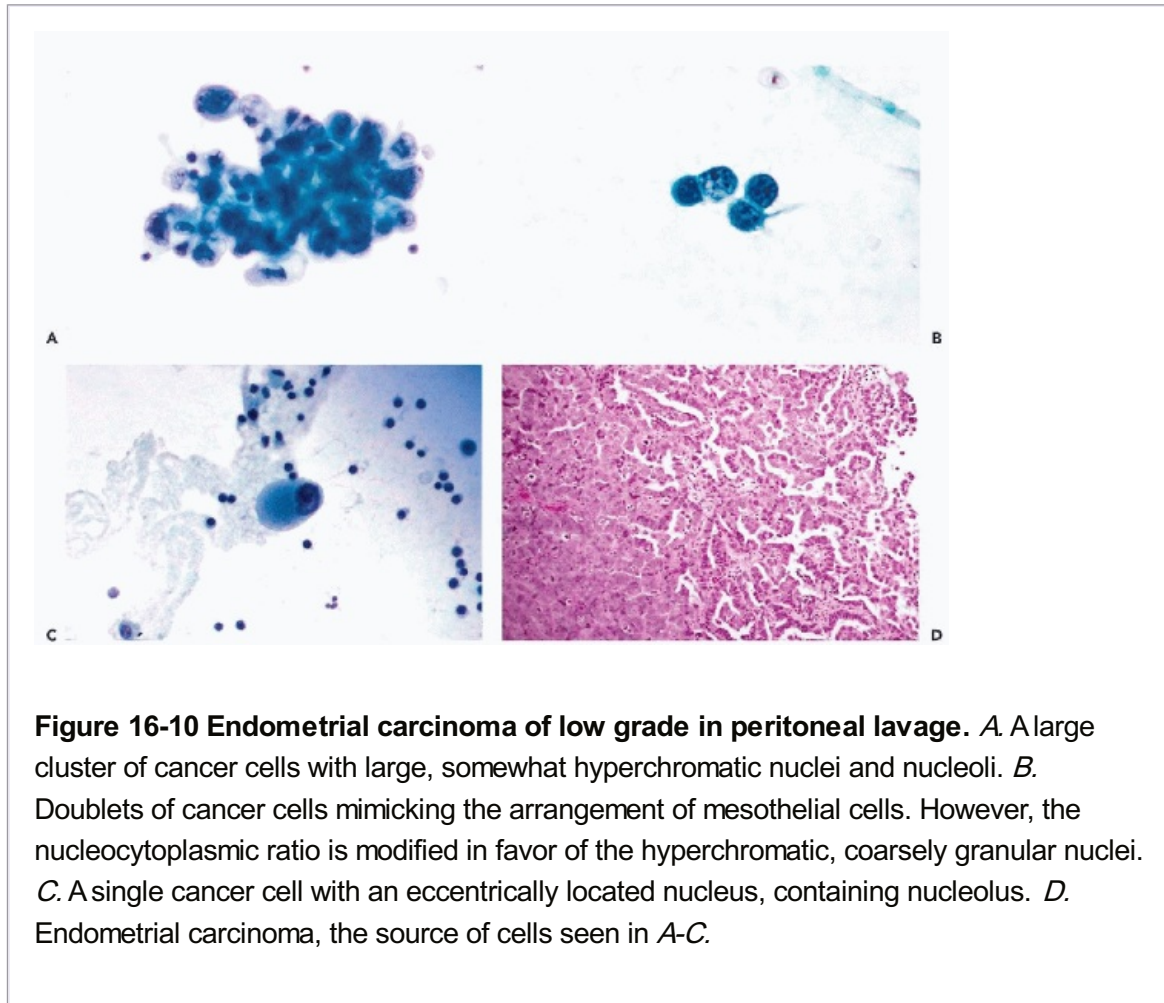

Coffin et al (1985) estimated that **diagnostic difficulties may occur in about one third of the second-look cases.** Biopsy evidence has shown that in many second-look procedures the residual cancer may be encased in foci of fibrosis, and hence not be accessible to peritoneal washings. Rubin and Frost (1963), on the basis of experience with 173 patients,

P.523

reported failure of the cytologic procedure to diagnose residual carcinoma in 66% of patients with overt disease and in 78% of patients with microscopic foci of residual cancer. These results appear pessimistic. Zuna et al (1989) reported significantly better results, with a failure rate in only about 30% of patients with documented residual cancer. Kudo et al (1990) reported positive lavage results in 8 of 18 patients with documented residual disease and in 4 of 23 patients without residual disease. However, three of the four patients with allegedly “false-

positive” results subsequently developed recurrent cancer and died of it. **It thus appears that the greatest value of the “second look” cytology is in an occasional detection of recurrences that escape the customary multi-biopsy evaluation.**

It is quite evident that the quality of the specimens, care in their preparation for cytologic study, and competence in the interpretation of the material may account for the variability of the results. Still, there is no evidence that the cytology of the peritoneal fluid in second-look surgical procedures can replace the standard multiple biopsies, though it may occasionally supplement them. To firmly establish the significance of pelvic lavage in these situations, a longterm follow-up study of patients after the “second look” procedure would be desirable.

PERITONEAL WASHINGS IN CANCERS OTHER THAN CANCER OF THE OVARY

Endometrial Carcinoma

The spread of endometrial cancers to the peritoneum of the cul-de-sac is probably more common than recognized so far. A particularly important culprit may be the relatively uncommon **serous papillary endometrial carcinoma** that may form metastases even if the primary tumor shows only superficial invasion of the myometrium. We have also observed several **adenoacanthomas** and **adenosquamous carcinomas** with relatively limited invasion of the myometrium and the presence of cancer cells in the peritoneal lavage.

Cytology

Endometrial **adenocarcinomas** can be recognized in lavage preparations as **clusters of**

malignant cells of various sizes, often of approximately spherical, papillary configuration, very similar to serous ovarian cancer. The cytoplasm of these cells is usually delicate and sometimes vacuolated. The nuclei are usually large, hyperchromatic, of irregular contour, and provided with clearly visible but not particularly large nucleoli (Fig. 16-10). The **serous-papillary endometrial**

P.524

carcinoma may shed cancer cells and cell clusters identical to those of serous ovarian carcinoma (Mesia et al, 1999). Single malignant cells have the same features as the cells in clusters. Sometimes, however, they are difficult to identify because of their similarity to atypical mesothelial cells and macrophages. **Similar cells are observed in ovarian endometrioid carcinomas.**

The **squamous component of adenoacanthomas and adenosquamous carcinomas** may have several different presentations. **Single squamous cancer cells** may be recognized within clusters of adenocarcinoma cells, or sometimes lying singly. As a general rule, these cells have **thick, sharply demarcated orange-staining cytoplasm** in a well-executed Papanicolaou stain. The **nuclei are sometimes large and hyperchromatic but more often are obliterated or seen as a pale nuclear outline (“ghost cells”).** Occasionally irregularly contoured **sheets of keratin-forming cells** may occur (Fig. 16-11). In our experience, **the combination of cells of adenocarcinoma and squamous cells in peritoneal lavage occurs only in endometrial carcinomas.** So far, we have never seen this association in other tumors but one can think of several candidate tumors, such as ovarian adenoacanthomas and endocervical adenocarcinoma with a squamous component.

In a very large study of 298 women with endometrial carcinoma, Gu et al (2000) compared positive peritoneal washings, observed in 32 patients with tumor type and stage. Ten percent of 262 patients with endometrioid carcinoma had positive washings, some with low stage and grade of disease. The frequency of positive washings for other tumor types (including serous carcinoma) was similar. The conclusions of the paper that positive peritoneal washing in endometrial cancer could not be correlated with stage, grade or histologic type of disease, is in keeping with several other studies cited in this paper and with personal experience.

Figure 16-11 Adenosquamous carcinoma of endometrium in peritoneal wash. A A

large cluster of cancer cells with hyperchromatic nuclei. *B.* Cancer cells forming a glandular structure (cell block). *C.* Clusters of squamous cells in the same peritoneal wash. *D.* The adenoacanthoma in a 33-year-old woman, corresponding to cells shown in *A-C*. (Case courtesy of Dr. David Burstein, Mount Sinai Hospital, New York, NY.)

Clinical Significance

Several publications on record suggest that the **presence of cancer cells in peritoneal lavage is of value in the prognosis of endometrial cancer, even of low stage and low grade** (Yazigi et al, 1983; Ide, 1984; Heath et al, 1988; Hirai et al, 1989; Mulvany, 1996; Zuna and Behrens, 1996). These authors reported increased mortality from endometrial cancer in the presence of cancer cells in the peritoneum. On the other hand, absence of cancer cells appears to be a favorable prognostic sign, although the rate of false negative examinations has not been established. Szpak et al (1981) correlated the number of malignant cells per 100 ml of washing fluid and documented a generally better response to therapy in patients with a low count of cancer

P.525

cells than in patients with a high count, although there were some exceptions.

However, several studies failed to attribute prognostic significance of positive peritoneal washings in stage I endometrial cancer (Lurain et al, 1989; Kadar et al, 1992; Gu et al, 2000). Still, there is little doubt that the procedure is desirable as part of a work-up of all patients with endometrial carcinoma. Still, a major follow-up study, taking into account response to therapy and long-term survival, may shed additional light on its clinical value.

Carcinomas of the Uterine Cervix

Peritoneal lavage in staging of squamous and adenocarcinomas of the uterine cervix has been the subject of several studies (Roberts et al, 1986; Morris et al, 1992; Patsner et al, 1992). A case of a small-cell, endocrine carcinoma was reported by Mulvany (1996). It is evident that **direct spread to the peritoneum occurs only in advanced, fully invasive carcinomas** and is not the preferred mode of spread of carcinoma of the cervix which tends to metastasize to lymph nodes.

Cytology

Cytologic findings depend on tumor type. **Well-differentiated squamous cancers of the cervix are virtually never observed in peritoneal lavage.** In **poorly differentiated squamous cancer**, the recognition of cancer cells is relatively easy. The cells occur singly and are characterized by **marked nuclear abnormalities and large nucleoli**. The presence of clusters of large, undifferentiated cancer cells usually corresponds to poorly differentiated squamous (epidermoid) carcinomas. In **adenocarcinomas**, clusters of **slender, columnar cancer cells** may be observed, sometimes forming **rosettes**. In the absence of clinical data it is virtually impossible to guess the origin of such cells that mimic any number of primary or metastatic tumors from various sites.

Figure 16-12 Tubal carcinoma with first clinical manifestation as a brain metastasis.

A,B. Cancer cells of a fallopian tube carcinoma in peritoneal lavage obtained at the time of hysterectomy. *C.* Metastatic adenocarcinoma to the brain which was ultimately traced to the fallopian tube. *D.* Carcinoma in situ of the fallopian tube. The tumor was invasive elsewhere.

Results

Roberts et al (1986) studied peritoneal washings in 139 patients with invasive carcinoma of the uterine cervix. Positive cytologic findings generally reflected high-risk factors, such as high stage of disease. Morris et al (1992) and Patsner (1992) expressed significant reservations about the value of peritoneal lavage in cervical cancers, particularly of low stage.

Carcinoma of Fallopian Tubes

The significance of peritoneal washings in carcinoma of the fallopian tubes has been underestimated. We observed a case of **occult tubal carcinoma** first observed as brain metastasis,

P.526

with positive peritoneal washings prior to salpingo-oophorectomy (Fig. 16-12). Several such cases were described by Agoff et al (2002) in patients with BRCA1 and 2 gene mutations. Mulvany (1996) reported the presence of cancer cells in 5 cases of **tubal carcinoma**, two of them with **psammoma bodies**.

Figure 16-13 Metastatic mammary carcinoma in pelvic lavage 6 years after mastectomy. *A*, large papillary clusters of cancer cells. In *B*, the handful of cancer cells is dispersed. *C, D*, The presence of tumor cells within the lumen of the fallopian tube under low power in *C*, higher power in *D*. (Case courtesy of Dr. Belur Bhagavan, Baltimore, MD.)

Other Primary Tumors

Geszler et al (1986) observed that the presence of cancer cells in stage I **mesodermal mixed tumors** (see Chap. 17) had a significant negative impact on prognosis. With growing experience other uncommon tumors of the female genital tract will be recognized in peritoneal lavage fluids.

Metastatic Cancers

Although uncommon, metastatic cancers from other sites may also be observed in peritoneal washings. In my experience, **mammary carcinoma is the most common offender**, although, other cancers are sometimes observed. Occasionally, the cancer cells reach the peritoneal cavity via the fallopian tubes and are discovered in peritoneal washings in the absence of visible metastases (Fig. 16-13). A case of metastatic melanoma of the vulva identified in peritoneal fluid was described by Izbán et al (1999).

Rare and Unusual Disorders of the Female Genital Tract

This chapter contains descriptions of uncommon benign and malignant lesions, that for the most part, may affect several component organs of the female genital tract.

RARE BENIGN DISORDERS

Deficiency of Folic Acid

Deficiency in folic acid (or vitamin B12) leads to impaired DNA synthesis during hematopoiesis, resulting in abnormal maturation of erythrocytes (and other blood cells) known as **megaloblastic anemia**. The disease is characterized mainly by a marked enlargement of erythrocytes and abnormalities of leukocytes. Folic acid deficiency may also impair DNA synthesis in other organs, such as the oral cavity and the gastrointestinal tract, where it can cause cellular enlargement (see Chaps. 21 and 24). In 1962 and 1966, Van Niekerk reported cell changes observed in **squamous cells in cervical smears** in patients with **megaloblastic anemia** and, hence, a folic acid deficiency, during the puerperium. The principal changes observed were generalized **enlargements of intermediate squamous cells** (diameter of 70 µm or larger), accompanied by an **enlargement of the nucleus** (diameter of 14 µm or more). Van Niekerk also observed **multinucleation** and **cytoplasmic vacuolization** in an average of 3.5% of cells. Other findings included phagocytosis, clumping, and folding of nuclear chromatin. The changes were apparently reversible after appropriate therapy. Van Niekerk's observations were generally confirmed by Klaus (1971), who considered **nuclear folding** as the most frequent event (6% of cells) and nuclear enlargement the second most frequent event (4% of cells). In Klaus' experience, the cytologic changes may be observed 8 to 10 weeks before clinical onset of megaloblastic anemia. Subsequently, Whitehead et al (1973) linked similar cell changes

P.529

with contraceptive therapy but the conclusive proof of this association is lacking.

Changes apparently caused by folic acid deficiency are deceptively similar to early neoplastic changes in the uterine cervix such as the **dyskaryosis (dysplasia)** of the superficial and intermediate squamous cells, **consistent with a low-grade squamous intraepithelial lesion, and abnormalities caused by a human papillomavirus infection** (see Chap. 11). It is of interest in this regard that folic acid deficiency may apparently enhance the patient's susceptibility to infection with human papillomavirus (Harper et al, 1994; Butterworth et al, 1992). Somewhat similar cell abnormalities may be observed as an **early effect of radiotherapy** (see Chap. 18). Because the cytologic follow-up of such lesions may be unreliable, it is prudent to have the patient undergo an appropriate work-up that should include a colposcopic evaluation of the uterine cervix before accepting the diagnosis of folic acid

deficiency as secure.

Pemphigus Vulgaris

Pemphigus vulgaris (from Greek, *pemphis* = blister) is a disorder usually affecting the skin and the mucous membranes of the oral cavity (see Chapter 21). It may sometimes involve the lower female genital tract. Several such cases were described in the gynecologic and dermatologic literature (see Krain et al, 1973). The disease is caused by **antibodies to desmoglein 3, a component protein of desmosomes** (Amagai et al, 1996) **causing a disruption of desmosomes in the lower layers of the squamous epithelium** leading to the formation of fluid-filled blisters, vesicles or bullae. The latter contain atypical squamous cells (**cells of Tznack et al, 1951**, who first described them) that can be observed in smears of broken vesicles. These are **squamous cells of bizarre shapes, sometimes with cytoplasmic protrusions, characterized by clear cytoplasm and nuclei and large nucleoli, occurring singly and in clusters. The antibodies coating these cells can be demonstrated by immunofluorescence**, as first shown by Beutner and Jordan in 1964. Libcke (1970) and Friedman et al (1971) each reported atypical squamous cells in cases of pemphigus vulgaris **involving the squamous epithelium of the cervix**. A number of additional cases of genital pemphigus, some also involving the vulva and vagina, were described (Kaufman et al, 1969). In a case described by Valente et al (1984), the atypical squamous cells were interpreted as suspicious, yet corresponded to clinically **occult pemphigus blisters** discovered in the hysterectomy specimen. In a case reported by Dvoretzky et al (1985), pemphigus was associated with a microinvasive carcinoma of the uterine cervix and, in a case reported by Krain et al (1973), with endometrial carcinoma. Because genital pemphigus can cause vaginal bleeding, it is obvious that a thorough examination of the female genital tract is required to rule out the possibility of a malignant tumor associated with this disease. For further discussion and illustrations of pemphigus, see Chapters 21 and 34.

Malakoplakia

This rare disorder of macrophages, unable to cope with colibacteria because of an enzymatic deficiency, is described in detail and illustrated in Chapter 22. The characteristic, **spherical cytoplasmic Michaelis-Guttman bodies** (representing enlarged and often calcified lysosomes), **observed in medium size macrophages, are diagnostic of this disorder in smears**. The findings in cervicovaginal smears were described in several cases of malakoplakia involving the **vagina and uterine cervix** (Lin et al, 1979; Chalvardijan et al, 1980; Wahl, 1982; Valente et al, 1984; Falcon-Escobedo et al, 1986). In an electron microscopic study, Kapila and Verma (1989) identified the characteristic coliform bacteria within the Michaelis-Guttman bodies in a case of cervical malakoplakia. Thomas et al (1978) described a case of this disorder involving the **endometrium** and causing abnormal bleeding.

Amyloidosis of the Cervix

A case of amyloidosis limited to the uterine cervix was reported by Yamada et al (1988). There are no known cytologic findings in this very rare disorder.

Eosinophilic Granuloma (Langerhans' Cell Granulomatosis)

This uncommon lesion, composed of Langerhans cells resembling macrophages and a mixture of eosinophilic polymorphonuclear leukocytes with other inflammatory cells, is known to involve the female genitals (Zinkham, 1976; Issa et al, 1980). There is no information on the cytologic

presentation of this lesion in cervicovaginal smears. For discussion of this entity in other organs, see Chapters 19 and 35.

Ectopic Prostatic Tissue in the Uterine Cervix

Larrazza-Hernandez et al (1997) and Nucci et al (2000) reported the presence of ectopic prostatic tissue in the uterine cervix, presenting in one case as a cervical mass (thought to be a fibroid) and in three cases as an incidental finding in tissue obtained for treatment of high-grade squamous intraepithelial lesions.

BENIGN TUMORS

Leiomyomas

These benign tumors of smooth muscle usually involve the myometrium of the body of the uterus and may reach substantial sizes. They are virtually always encapsulated and do not normally shed any cells in cytologic samples from the uterus. Occasionally, however, ulcerated leiomyomas of the uterus, particularly if located in the uterine cervix, may shed **benign smooth muscle cells** that can be recognized in cervicovaginal smears. These slender cells are **spindly, elongated, usually occur in parallel bundles, and show oval, finely granular nuclei**, often located in the approximate center of the cell. Similar cells may be sometimes observed following **abortion** and after a **mechanical injury to the**

P.530

cervix (see Chap. 8). **Endometrial abnormalities** may occur in the presence of large leiomyomas (see Chap. 13).

Other Benign Tumors

Other benign tumors of the uterus, vulva or vagina, such as **rhabdomyoma** (Gad and Eusebi, 1975; Gold and Bossen, 1976), **syringoma** (Young et al, 1980), **glomus tumor** (Spitzer et al, 1985), and **granular cell tumor** (Coates and Hales, 1973), are exceedingly rare and they have not been observed in smears. Granular cell tumors of the breast, and sometimes of other organs, may be recognized in aspiration biopsies (see Chaps. 20 and 29).

RARE MALIGNANT TUMORS

Sarcomas

Sarcomas and other malignant tumors of mesenchymal origin constitute about 2% to 3% of all malignant tumors of the female genital tract. Their most common primary site is the uterine corpus, followed by the cervix and vagina. Most sarcomas are **homologous** (i.e., made up of a single tissue type, such as smooth or striated muscle or fat). However, a substantial number of malignant mesenchymal tumors of the uterus, known as the **mesodermal or Müllerian mixed tumors**, contain a **mixture of epithelial and sarcomatous** components. The histologic and cytologic aspects of these and other sarcomas are discussed below.

Most sarcomas originate within the depths of the affected organ and do not reach the exfoliating surface until they have grown to a substantial size and have produced surface ulceration. In the vast majority of such cases, the patients are symptomatic and have clinically obvious disease. Thus, **routine cytologic examination of the female genital tract rarely contributes to the primary diagnosis of these tumors, except for the mesodermal mixed tumor**. In most cases, the role of cytology is relegated to the **recognition of recurrent**

disease. In many instances, even this exercise is fraught with considerable difficulty. Occasionally, however, cytologic evaluation may contribute to the diagnosis and clinical handling of the patient.

Tumors of Smooth Muscle (Leiomyosarcomas)

Histology

Leiomyosarcomas are the most common sarcomas of the female genital tract. Nearly all tumors originate in the smooth muscle of the uterine corpus, although they may be primary in the muscle of the uterine cervix and, exceedingly rarely, in other genital organs such as the fallopian tube or the wall of the vagina. The tumors are composed of **crisscrossing bundles of abnormal smooth muscle cells**, characterized by large, hyperchromatic nuclei. Several rare variants of these tumors are known to occur, chief among them the **epithelioid leiomyosarcoma**, a tumor composed of large, polygonal cells mimicking an epithelial tumor. The prognosis of uterine leiomyosarcomas depends on the size of the tumor, its relationship to adjacent organs, and its histologic differentiation or grade. Small tumors incidentally found within the myometrium or arising within benign leiomyomas generally offer an excellent prognosis. However, tumors attached to adjacent viscera are often fatal, regardless of grade. **Well-differentiated tumors**, closely resembling benign leiomyomas, except for nuclear abnormalities and sometimes high mitotic count (**grade I**), usually have a much better prognosis than tumors composed of bundles of clearly malignant cells (**grade II**). Highly disorganized tumors made up of bizarre large or small cancer cells (**grades III and IV**) have a nearly uniformly fatal prognosis (Spiro and Koss, 1965; Bodner et al, 2003). Voluminous literature pertaining to the classification and recognition of leiomyosarcomas, particularly the differentiation between atypical leiomyomas and low-grade leiomyosarcomas (Bell et al, 1994), has very limited bearing on cytologic observations.

Cytology

Massoni and Hajdu (1984) stressed the very low rate of primary leiomyosarcomas recognized in cervicovaginal material. **Cells from the well-differentiated forms of leiomyosarcoma (grade I) have never been seen by us or identified in routine smears.** However, more anaplastic forms of this tumor (grades II through IV), once ulcerated or metastatic, may shed **highly abnormal, often grotesque cancer cells. If such cells are elongated, as is sometimes the case, a more specific diagnosis of tumor type may be attempted** (Fig. 17-1). Single or multiple abnormal nuclei of variable sizes may be noted. **Nuclear hyperchromasia is variable, and irregular, large nucleoli may be present.** The difference between cells of a high grade leiomyosarcoma and normal smooth muscle cells is obvious. Quite often, however, cancer cells shed from a leiomyosarcoma are **polygonal rather than elongated and may be mistaken for cells of a carcinoma.**

Elongated, spindly, or bizarre malignant cells are not unique to leiomyosarcomas and may occur in other sarcomas and in mesodermal mixed tumors. Similar cells may also occur in invasive epidermoid carcinomas, particularly of the spindle- and giant-cell variety (see below).

Klijanienko et al (2003) reported a large series of leiomyosarcomas of various types and primary extrauterine locations, diagnosed by direct thin needle aspiration. To my knowledge, no attempts have been made to apply this technique to uterine tumors.

Tumors of Striated Muscle (Rhabdomyosarcomas)

Although the female genital tract does not normally contain striated muscle, isolated cells of this type may occasionally be found in benign myometria. This, however, is not an essential prerequisite for the occurrence of rhabdomyosarcoma, which apparently may originate from any type of mesenchymal cell. **Pure embryonal-type sarcomas of striated muscle origin are most commonly observed in the vagina or the cervix of young children and young adults as botryoid sarcomas** (Daya and Scully, 1988). Occasional rhabdomyosarcomas of **alveolar type** have been observed in other organs of the female genital tract, for example, in the uterine corpus (Donkers et al, 1972) and the vulva (Imachi et al, 1991).

P.531

Rhabdomyosarcomas are a **common component of mesodermal mixed tumors** (see below).

Figure 17-1 Leiomyosarcomas. *A-C.* Bizarre cancer cells at high magnification from two patients with recurrent tumor. *D.* The histologic appearance of the tumor corresponding to *A* and *B*. The diagnosis of a poorly differentiated malignant tumor could be easily made but the specific diagnosis of a leiomyosarcoma could not be established in the absence of past history.

Botryoid sarcoma (from the Greek, *botrys* = bunch of grapes) is a form of immature (embryonal) rhabdomyosarcoma that forms **grape-like, translucent tumor nodules** usually in the vagina, much less commonly in the uterine cervix of young girls, who are rarely older than five years of age, but sometimes also in young adults. Similar tumors may occur in the **urinary bladder of children of both sexes** and in the **prostate** of boys. The grape-like structures are surfaced by an intact squamous epithelium. The tumor cells form a **dense subepithelial layer** (cambium layer) composed of very small cancer cells, surrounding the loosely structured bulk of the tumor wherein larger **cancer cells, some with cytoplasmic cross-striations** or marked cytoplasmic eosinophilia, may be identified.

Previously considered nearly invariably fatal (Daniel et al, 1959), the tumors are now curable in a large proportion of cases with a combination of radiotherapy and chemotherapy (review in

Brand et al, 1987). Daya and Scully (1988) stressed better prognosis of botryoid sarcoma of the uterine cervix in young adults than in children.

Cytology

The diagnosis of primary botryoid sarcomas is usually made by clinical inspection and biopsy. Cytologic diagnosis is superfluous in such instances. Even if vaginal smears are obtained, the tumor cells may be absent because of the protective epithelial layer. However, in recurrent and in metastatic tumors, small, elongated, spindly tumor cells may be observed in vaginal smears or in urinary sediment (see Chap. 26). In rare instances, cytoplasmic cross-striations may occur that allow a precise classification of the tumor.

Differentiated rhabdomyosarcomas are very rare in the female genital tract (Brand et al, 1989). One can then anticipate the finding of bizarre tumor cells with cytoplasmic cross-striations, characteristic of rhabdomyoblasts (see Fig. 17-6). The cytologic findings in two cases of alveolar rhabdomyosarcoma of the vulva were reported by Imachi et al (1991), who did not observe cytoplasmic striations in the tumor cells.

Endometrial Stromal Sarcomas

The endometrial stromal tumors originate either in the endometrium or in foci of uterine endometriosis (adenomyosis). There are two presentations of this tumor: a low-grade and a high-grade tumor.

Histology and Clinical Features

The low-grade, well-differentiated form of the tumor (previously named the endolymphatic stromal myosis) is composed

P.532

of orderly bundles of small cells similar to endometrial stroma, sometimes forming ribbon-like organoid structures (so called "plexiform tumorlets") and occasionally small glands, mimicking primitive endometrial glands. Clement and Scully (1989) misinterpreted the "tumorlets" for sex cord-like elements, seen in rare ovarian tumors, but the origin of these structures from endometrial stroma has been clearly documented by Larbig et al (1965). The tumor cells may occasionally differentiate into smooth muscle cells, particularly in metastatic foci. Oliva et al (2001) pointed out that cells with markedly eosinophilic cytoplasm may occur in such tumors. The tumor has several other interesting features: it has the tendency to invade vessels of the uterus and adjacent pelvis, sometimes forming solid, spaghetti-like cylinders that can be pulled from the affected vessels by a forceps. For this reason, the tumor may be confused with intravenous leiomyomatosis, as in a paper by Clement et al (1988). The tumor may have an erratic, protracted clinical course, stretching over a period of many years (Koss et al, 1965). It may form local, retroperitoneal, or distant metastases, for example, to the bladder or lung, often many years after surgical removal of the primary tumor (28 years in a personally observed case), and still be consistent with long-term survival following aggressive treatment of metastases. Late pulmonary metastases were also described by Abrams et al (1989). The tumor may also respond to hormonal manipulation with progesterone, not unlike an endometrial carcinoma. Because of the unusual, often favorable behavior of this tumor, its diagnosis in metastatic foci may be life-saving.

The high grade endometrial stromal sarcomas are infrequent. In a small series by Koss et

al (1965), only 1 of 10 stromal sarcomas could be so classified. The tumor has a similar distribution to the low-grade variant but is composed of obviously malignant larger cells and has aggressive behavior.

Cytology

Several examples of this tumor were described in cervicovaginal smears (Hsiu and Stawicki, 1979; Becker and Wong, 1981) and in other cytologic samples such as effusions (Massoni and Hajdu, 1984; Hajdu and Hajdu, 1976). So far as one can tell, the reported cases represented the **high-grade variant of the disease**. In general, the authors stressed the **small size and the relatively monotonous appearance of the round or oval malignant cells**, accompanied by occasional elongated cells with tapering cytoplasm, named **comet cells** by Hsiu and Stawicki (1979). Except for hyperchromasia and variability in size, the nuclei had no distinguishing features. Mitotic figures were observed in two of three cases reported by Becker and Wong (1981). In all cases described, the tumor was far advanced and symptomatic; all patients, save one, died of disease shortly after diagnosis.

There are no reported cases of primary diagnosis of the **low-grade stromal sarcoma**. However, **metastases** of this tumor may be amenable to diagnosis by needle aspiration biopsy that may lead to aggressive treatment and long-term survival. As an example, the aspirate of one of many **large, cannon-ball pulmonary metastases** in a 38-year-old woman contained **small, spindly, rather benign-looking cells and scattered glands, resembling benign endometrial glands** (Fig. 17-2). The cytologic finding led to the review of hysterectomy material obtained 8 years previously, which was initially diagnosed as a benign abnormality (stromal nodule). The review disclosed a low-grade endometrial stromal sarcoma. After surgical removal of all but one of the pulmonary metastases, followed by progesterone therapy, the patient remained well for several years without any evidence of active disease. In another more recent case with only short follow-up, the aspirate of lung metastases yielded small cells resembling normal endometrial stroma (Fig. 17-3).

Other Sarcomas

Exceedingly uncommon sarcomas may be observed in the female genital tract.

Epithelioid sarcomas are very rare sarcomas of soft tissue that characteristically mimic epithelial tumors, hence their name. A few cases of this disease involving the vulva were reported in the cytologic literature (Ulbright et al, 1983; Hernandez-Ortiz et al, 1995). In aspirated material, the authors reported the presence of **polygonal malignant cells with eosinophilic cytoplasm**, large nuclei and prominent nucleoli, mimicking cells of a clear cell carcinoma. It is unlikely that an accurate cytologic diagnosis of these tumors can be established in the absence of clinical history.

A case of **malignant fibrous histiocytoma of the cervix**, with cytologic findings, was described by Fukuyama et al (1986). The cytologic features included **multinucleated and elongated (spindly) cancer cells**. Zaleski et al (1986) and Foschini et al (1989) each reported a case of **alveolar soft-part sarcoma of the vagina**. In keeping with the pseudoepithelial histologic appearance of this tumor, **large malignant cells, with eosinophilic granular cytoplasm, singly and in clusters**, were observed in the cervicovaginal smears. The nuclei were eccentric and provided with large nucleoli. Characteristic **intracytoplasmic crystalloids** were documented by periodic acid-Schiff (PAS)-stain and by electron microscopy.

An **osteosarcoma**, a **liposarcoma**, and a **Wilms' tumor of the uterine cervix** were

described (Bloch et al, 1988; Bell et al, 1985; Brooks and LiVolsi, 1987) but there is no information on their cytologic presentation in this anatomic location. A **synovial sarcoma-like** tumor of the vagina was described by Okagaki et al (1976). For cytologic presentation of sarcomas of various types and organs in aspiration biopsies, see Chapter 35.

Malignant Mesodermal Mixed Tumors (Müllerian Mixed Tumors)

The highly malignant mesodermal mixed tumors are most often of **endometrial origin; similar tumors, however, may also occur in the uterine cervix, fallopian tube, the ovary, and organs of other than Müllerian origin, such as the urinary bladder** (Mortel et al, 1974; Dictor, 1985; Wu et al, 1973; see also Chapter 23). Hence, the commonly used term “Müllerian mixed tumors,” is not accurate. In the female genital tract, the most common mesodermal mixed tumors of the endometrium occur chiefly in the menopausal age group and often appear clinically as **polypoid lesions, sometimes protruding through the external os of the cervix.**

P.533

Figure 17-2 Endometrial stromal sarcoma metastatic to lung in a 38-year-old woman. *A.* The original uterine tumor observed in 1975. The tumor was composed of small, spindly cells and formed small glands. The diagnosis of “stromatosis” was established. *B.* The chest x-ray of this patient in 1983 showing multiple cannonball-type metastases. *C,D.* Aspiration smears of a pulmonary lesion. *C.* A low-power view of the aspiration smear showing clusters of epithelial cells and a few scattered spindly cells. *D.*

Epithelial clusters resembling benign endometrial glands. *E.* Resected pulmonary nodule showing a histologic pattern somewhat similar to the original uterine tumor shown in *A*. Elsewhere the metastases differentiated into smooth muscle. *F.* The metastatic foci formed gland-like structures which were reflected in the aspiration biopsy shown in *C* and *D*. This patient is known to have survived 10 years after the resection of the pulmonary nodules.

P.534

Figure 17-3 Endometrial stromal sarcoma metastatic to lung. *A.* The aspiration of the lung nodule. The smear is composed mainly of short spindly cells without conspicuous nuclear abnormalities. *B.* A biopsy of pulmonary nodule showing endometrial stromal sarcoma forming glands.

When these tumors show only elements of **carcinoma with spindle cell stroma**, they are usually classified as **carcinosarcomas or spindle cell carcinomas** (see below).

Figure 17-4 Mesodermal (Müllerian) tumor of the uterus. *A.* Clusters of epithelial cells resembling a poorly differentiated carcinoma. *B.* Spindly cells, some of which had cross striations in the cytoplasm. *C.* Histology of tumor shown in *A* and *B*. In this field, one can

observe poorly differentiated carcinoma with focal squamous differentiation and a fragment of chondrosarcoma. In *D*, striated spindly cells brought out by trichrome stain reflect the presence of a rhabdomyosarcoma.

Histology

These tumors **are composed of a mixture of undifferentiated and differentiated sarcomas and carcinomas. The most common differentiated sarcoma is rhabdomyosarcoma** (see Fig. 17-4C,D). Other sarcomatous elements may resemble endometrial stromal sarcoma, leiomyosarcoma,

P.535

chondrosarcoma, or liposarcoma (see Fig. 17-5D). The carcinomatous components are in the form of adenocarcinoma, squamous carcinoma, or a mixture of both. Clement and Scully (1974) identified a subvariant of mesodermal mixed tumors in which the epithelial component was morphologically benign and named it **adenosarcoma**. However, the behavior of adenosarcoma was similar to that of malignant mesodermal mixed tumor. In 1989, the same authors described a very rare variant of mesodermal mixed tumor with **sex-cord-like elements**. An exceedingly rare, histologically benign variant of mesodermal mixed tumor has been described (Vellios et al, 1973; Demopoulos et al, 1973).

Figure 17-5 Mesodermal (Müllerian) mixed tumor of the uterus. *A*. Sheets of poorly differentiated malignant epithelial cells. *B*. A cluster of malignant cells suggestive of a squamous pearl. *C*. A few elongated cancer cells and a few cancer cells, most likely corresponding to the undifferentiated component of the tumor. *D*. The histology of one area of the tumor composed mainly of small, poorly differentiated cells and a poorly differentiated carcinoma forming a squamous pearl.

Cytology

The mesodermal mixed tumors may sometimes be recognized in cervicovaginal smears prior to

clinical diagnosis. The **background of the smears** is usually filled with necrotic material and fresh and old blood. Fully developed mesodermal mixed tumors usually shed abundant cancer cells (Figs. 17-4 and 17-5). The **predominant malignant cells** are usually **small, of uneven size, round or elongated, with scanty cytoplasm and relatively large, hyperchromatic nuclei, wherein conspicuous nucleoli can often be seen**. Elongated, spindle-form small malignant cells may also occur. These cells correspond to the sarcomatous component of these tumors, made up of small cells. Cells of **coexisting carcinomas resemble those of endometrial carcinoma, squamous carcinoma, or both. Sometimes, carcinoma cells are the only malignant component observed in smears**. More often, however, there is an association of elements of adeno- or squamous carcinoma with the small malignant cells described above, which is fairly characteristic of mesodermal mixed tumor. Cells of **rhabdomyosarcoma**, showing **cytoplasmic cross-striations** or at least markedly eosinophilic cytoplasm, are rarely seen. When they occur, however, they are diagnostic of **rhabdomyosarcoma** which, in most cases, is a component of a mesodermal mixed tumor (Fig. 17-6). Identifiable cells from other forms of sarcoma, such as **chondrosarcoma**, are exceedingly rare.

Mesodermal mixed tumor should be differentiated from **endometrial or cervical carcinomas with undifferentiated components**, which may be made up of spindly and giant tumor cells, thereby suggesting a co-existing sarcoma. Such tumors are often referred to as **carcinosarcomas**, but the name **spindle-cell or spindle- and giant cell carcinoma** appears more appropriate (see below). The prognosis of these tumors is better than that of mesodermal mixed tumors (Norris and Taylor, 1966; Mortel et al, 1974). The

P.536

separation of mesodermal mixed tumors from undifferentiated carcinomas in limited biopsy material may be very difficult.

Figure 17-6 Ascitic fluid with metastatic mesodermal (Müllerian) mixed tumor of the uterus. Cytoplasmic cross striations are indicative of a rhabdomyosarcoma-like element in the tumor. Oil immersion magnification. (Case courtesy of Dr. Misao Takeda, Jefferson Medical College, Philadelphia, PA.)

Current classification of malignant lymphomas is discussed in Chapter 31. **Primary malignant lymphomas** of the female genital tract are uncommon and only sporadic cases of such tumors occurring in the uterine cervix, vagina or ovary were recorded prior to 1980 (Johnson and Soule, 1957; Vieaux and McGuire, 1964; Iliya et al, 1968; Buchler and Kline, 1972; Katayama et al, 1973; Stransky et al, 1973; Delgado et al, 1976; Carr et al, 1976; Whitaker, 1976; Krumermann and Chung, 1978; Tunca et al, 1979). Within recent years, additional cases of primary malignant lymphomas of the uterine cervix have been reported (Komaki et al, 1984; Harris and Scully, 1984; Taki et al, 1985; Mann et al, 1987; Strang et al, 1988; Andrews et al, 1988; Perren et al, 1992; Clement, 1993; Gabriele and Gaudiano, 2003). We have personally observed several examples of malignant lymphoma of the uterine cervix and vagina. **Vaginal bleeding** may be the first manifestation of this group of diseases.

Figure 17-7 Large cell malignant lymphoma primary in the uterine cervix. *A,B.* Cervical smears showing dispersed cells of lymphocytic lineage with prominent large nucleoli. *C,D.* Aspects of the cervical lymphoma which was originally misinterpreted as a poorly differentiated carcinoma.

Cytology

The cytologic recognition of **small-cell malignant lymphomas** (or chronic lymphocytic leukemias which have identical presentation) in cervicovaginal smears is difficult. The cytologic samples contain a monotonous population of small lymphocytes without distinguishing features, except for **granularity of the nuclei and irregularities of the nuclear contour**. Young et al (1985) cautioned that benign inflammatory lymphoid infiltrates of the cervix, endometrium, and vulva may mimic malignant lymphomas. Lymphocytic cervicitis (see Chap. 10) is a case in point. The presence of polyclonal plasma cells and lymphocytes or polymorphonuclear leukocytes within the lymphocytic

P.537

lesion should be construed as a warning that the lesion may be inflammatory.

The cytologic presentation of **primary large-cell lymphomas** is identical with that of

secondary involvement (described in detail in Chaps. 26 and 31). The malignant cells, with nuclei rarely larger than 15 µm in diameter, **are dispersed and, as a rule, do not form clusters**. The cells **vary somewhat in size, have scanty cytoplasm and have stippled, occasionally folded, cleaved, or creased nuclei that are often provided with large nucleoli** (Fig. 17-7). Occasionally, the **nuclei may form small nipple-like protrusions** that should be distinguished from similar protrusions occurring in the much larger columnar endocervical cells (see Chap. 8). The most important **differential diagnosis** of large cell lymphomas is with **poorly differentiated carcinomas**. In the latter, clustering and molding of malignant cells is commonly seen and the nuclei are rarely cleaved or creased. Still, it is advisable to use **immunocytochemistry** to determine the nature of the tumor. This was described, with impressive results, in two more recent papers on this topic (Matsuyama et al, 1989; Dhimes et al, 1996).

The **difficulties in the differential diagnosis of large-cell lymphomas** of the cervix may **extend to the biopsy material**. Before the era of immunologic markers, large-cell lymphomas were repeatedly mistaken for anaplastic small cell carcinomas treated by surgery, occasionally with disastrous consequences for the patient. An abnormality of **decidual cells** in the cervix, **mimicking a large cell lymphoma** (reticulum cell sarcoma in the original article) has been reported by Armenia et al (1964).

Nasiell (1964) presented a well-documented case of **Hodgkin's disease**, apparently confined to the cervix, with a primary diagnosis by cervical smear. **Multinucleated tumor cells, similar to Reed-Sternberg cells**, were described (Fig. 17-8). A similar case was described by Uyeda et al (1969).

Granulocytic Sarcoma (Chloroma)

This tumor-like manifestation of chronic myelocytic leukemia may occur in the female genital tract. The tumor may appear greenish on gross presentation because of the presence of myeloperoxidase in tumor cells and, hence, were named **chloroma** (from Greek, *chloros* = green). Abeler et al (1983) described two cases of this disease affecting the uterine cervix. Oliva et al (1997) described 11 patients with this disorder, affecting the female genital tract, mainly the **ovaries** (7 cases), but also the **vagina** (3 cases) and, in one case, the **uterine cervix**. The diagnosis was confirmed by histochemistry, disclosing enzymes and products characteristic of myelogenous leukemia. Spahr et al (1982) were the first to describe the cytologic presentation of this condition in the cervix, diagnosed by **cervical smears prior to clinical evidence of chronic myelogenous leukemia**. The smear was characterized by the presence of highly **abnormal large cells, mimicking malignant lymphoma**, but with **eosinophilic cytoplasm that gave a positive reaction for Leder's esterase**, a characteristic histochemical reaction for myelogenous leukemia. At autopsy, the diagnosis of chloroma of the uterus and bowel was established; the bone marrow showed pre-leukemic abnormalities. A similar case was described by Kapadia et al (1978) in an elderly patient with known acute myelocytic leukemia. An example of this entity is illustrated in Chapter 27.

Figure 17-8 Primary Hodgkin's disease of the uterine cervix in a 39-year-old woman. Primary diagnosis by smear. *A.* Cervical smear showing a multinucleated cancer cell with large nucleoli and a few mononucleated cells showing similar nuclear features. *B.* Histologic presentation of cervix lesion. The patient was free of disease 3 years after hysterectomy. (From Nasiell M. Hodgkin's disease limited to the uterine cervix: A case report including cytological findings in the cervical and vaginal smears. *Acta Cytol* 8:16-18, 1964.)

Neuroendocrine Tumors

Histology

This group of tumors of the uterine cervix may have variable morphologic characteristics, ranging from the rare classical **carcinoid tumors** (Albores-Saavedra et al, 1976; Walker and Mills, 1987; Seidel and Steinfeld, 1988), to **carcinomas resembling small cell squamous carcinomas**, to the highly malignant variant resembling **oat cell carcinoma** (Johannessen et

al, 1980; Walker et al, 1988). The term **neuroendocrine carcinomas** has been applied to some of these tumors. The **common denominator** of these tumors is the presence of **cytoplasmic neurosecretory granules** in electron microscopy and immunochemical reactions documenting the presence of endocrine activity, such as **chromogranin, serotonin, and synaptophysin**. Such tumors may also occasionally occur in the endometrium and the ovary. The endocrine activity of the vast majority of these tumors has no clinical significance. As discussed in Chapter 11, in an exceptional case, the **endocrine function of these tumors may have systemic effects**, as in a case of **serotonin-producing cervical carcinoid** (Hirahatake et al, 1990) or an **insulin-producing cervical, small cell carcinoma**, causing hypoglycemia (Seckl et al, 1999). It must be added that metastatic carcinoma of the cervix to the pituitary may cause **diabetes insipidus** (Salpietro et al, 2000).

P.538

Figure 17-9 Histologic presentation of a lymphoepithelioma-like tumor of the uterine cervix in a 33-year-old Chinese woman. The keratin stain in *B* shows the epithelial component of the tumor which is obscured in *A* by the proliferation of lymphocytes. (Case courtesy of Prof. Shanmugaratnan, Singapore.)

Figure 17-10 Spindle and giant cell carcinoma of cervix. *A.* Tumor cells in spindly configuration. *B.* Multinucleated giant cells observed in the same smear. *C.* The overall structure of the invasive tumor topped by a carcinoma in situ. *D.* Detail of tumor stroma composed of spindly cells with numerous giant cells.

P.539

It has now been shown that **neuroendocrine features**, such as neuroendocrine granules and corresponding immunohistologic reactions, can be observed in about **one-third of invasive cervical carcinomas of various types**, but mainly of the small-cell type (Barrett et al, 1987; van Nagell et al, 1988). The endocrine features have no bearing on the diagnosis. In some of these tumors, squamous carcinoma in situ has been observed in adjacent epithelium (Johannessen et al, 1980), although this feature has not been stressed by other observers. Groben et al (1985), Seidel and Steinfeld (1988), and Stoler et al (1991) commented on the poor outcome of such tumors, even if diagnosed at low initial stage. Stoler et al (1991) observed the presence of **HPV type 18, and sometimes type 16**, in 18 of 20 endocrine carcinomas.

Cytology

In view of the diversity of morphologic types of cervical carcinomas with endocrine features, it is not surprising that their cytologic presentation is equally diverse. In general, these tumors **cannot be identified in smears as having neuroendocrine features**. In most cases, the cells in smears have the features of **high-grade carcinoma composed of small cells**, described in Chapter 11. In a case described by Miles et al (1985), the cancer cells in the cervical smear had the appearance of **cells of an epidermoid carcinoma and adenocarcinoma, next to undifferentiated cancer cells**. Although the presence of neuroendocrine granules was documented in the tumor and a positive reaction to serotonin was observed in the exfoliated cells, the morphologic appearance of the tumor was that of an adenosquamous carcinoma. Russin et al (1987) reported another case that had the cytologic

presentation of an **adenocarcinoma with psammoma bodies**. In a case of **carcinoid of the uterine cervix**, Hirahatake et al (1990) described a population of small malignant cells with granular nuclei and prominent nucleoli and, hence, cytologic features not specific for carcinoid tumors (see Chaps. 11 and 20). Reich et al (1999), describing a case of malignant carcinoid in an 18-year-old woman, stressed **molding of tumor cells**, a feature commonly observed in oat cell carcinoma (see Chap. 20).

Lymphoepithelioma-Like Cervical Carcinoma

A rare tumor of the cervix in which **undifferentiated cancer cells were accompanied by a large population of lymphocytes** was observed by us in a young Chinese patient in the 1970s. The cytoplasm of the carcinoma cells was strongly positive with keratin antibodies. The tumor had a **striking similarity to a nasopharyngeal tumor**, known to occur with high frequency among Chinese, particularly from the southern provinces of China (see Chap. 21). Similar tumors of the uterine cervix were initially described by Mills et al (1985) and Hafiz et al (1985), and subsequently by several other observers (Halpin et al, 1989; Weinberg et al, 1993; Tseng et al, 1997; Reich et al, 1999) (Fig. 17-9). **Epstein-Barr virus (EBV)**, which is often associated with nasopharyngeal tumors of this type, was observed by Tseng et al (1997) in 11 of 15 cases of cervical tumors, but also the presence of HPV in four of them. Noel et al (2001) were unable to identify EBV but confirmed the presence of HPV in two additional patients.

Reich et al (1999) described the **cytologic features** of one such tumor in cervicovaginal smears. The dominant feature was the presence of **large, pale cancer cells** with prominent nucleoli, **accompanied by numerous lymphocytes** and, hence, identical to the cytologic presentation of the nasopharyngeal tumors, described in Chapter 21. Proca et al (2000) described the cytologic findings in two patients with advanced tumors of this type. The findings were not specific.

Spindle and Giant Cell Carcinomas (Carcinosarcomas)

Histology

Rare cancers of the uterine cervix, vagina and endometrium may show unusual patterns, such as **spindle cell configuration, often accompanied by multinucleated giant cells (spindle and giant cell carcinoma sometimes referred to as “carcinosarcoma”)**. In the **cervix or vagina**, such tumors always contain a component of **squamous cancer**, either in the form of a high-grade precursor lesion on the surface of the tumor (HGSIL) or as nests of keratin-forming tumor cells within the invasive tumor and, therefore, must be considered as variants of squamous carcinoma. Grayson et al (2001) reported the presence of HPV type 16 in three of eight tumors. Of special interest was the presence of the virus in the sarcomatous component of the tumors, documenting still further that the spindly cells are merely a variant of squamous cancer. Spindly cell tumors with a glandular component are also observed in the endometrium (Mortel et al, 1974). It is generally thought that such tumors are variants of malignant mesodermal mixed tumors, described above.

Cytology

The cytologic appearance of these rare tumors is characteristic: **in cervicovaginal smears**, the tumors shed **spindly tumor cells and multinucleated giant cells, usually accompanied by scattered asquamous cancer cells** (Fig. 17-10). We have not observed any other tumors with these cytologic features.

Figure 17-11 Adenoid-cystic carcinomas of cervix. *A.* Low-power view of the tumor which is associated with a squamous carcinoma. *B.* Details of another tumor in which the configuration of the cystic spaces is well shown. Cytologic presentation of this tumor is discussed at length in Chapter 32.

Merkel Cell Carcinoma of the Vulva

A case of this most unusual tumor, with extensive metastases, was reported by Bottles et al (1984). For description of histologic and cytologic features of Merkel cell carcinoma, see Chapter 34.

Adenoid Cystic Carcinomas

Clinical Data

These are rare but highly malignant tumors of the uterine cervix, occurring mainly in women past the age of 60. Prempreet et al (1980) documented that even for tumors of clinical stage I, the five-year postsurgical survival was only 50% to 70%, even after radiotherapy. For tumors of higher stages, there were virtually no 5-year survivors in a compiled series of 43 patients. Ferry and Scully (1988) documented that these tumors have a more aggressive behavior pattern than their counterparts in the salivary glands (see Chap. 32). Thus, the **adenoid cystic carcinoma of the cervix must be considered a highly lethal tumor**, at par with the more common tumors of this type in the salivary glands (see Chap. 32). The tumor may occur in women of all ages but also in younger women (De La Maza et al, 1972; Ramzy et al, 1975; King et al, 1989). A case of metastatic adenoid cystic carcinoma of cervix to the lung, mimicking primary bronchial tumor, was reported by Ryden et al (1974).

Figure 17-12 Basaloid cystic carcinoma of cervix. *A.* Carcinoma in situ on the surface of the cervix was the source of abnormal cells in smears. *B.* An area of basaloid-cystic carcinoma adjacent to carcinoma in situ. The tumor was infiltrating but showed no evidence of recurrence after removal. (Case courtesy of Dr. William Hart, The Cleveland Clinic, Cleveland, OH.)

Histology

The tumor is characterized by **densely packed, uniform small cancer cells, forming extracellular, cyst-like spaces, filled with eosinophilic homogeneous material** consisting of **reduplication of basement membrane**. The tumors also contain small glandular structures producing mucus (Fig. 17-11). Morphologically, the tumors are similar to a common **carcinoma of salivary gland origin** (Ferry and Scully, 1988). **Similar tumors** may be occasionally observed in **the breast, bronchus, prostate and other sites**. When first described by the surgeon Billroth in the 1880s, the tumors were thought to be relatively benign with emphasis on the

P.541

cylindrically-shaped spaces within the tumor, hence the name ***cylindroma***. In spite of slow evolution, the tumors are fully capable of metastases. In the **uterine cervix**, the adenoid cystic carcinomas are **commonly associated with squamous carcinoma in situ or invasive squamous cancer** and thus must be considered a rare variant of squamous carcinoma of the cervix (Ravinsky et al, 1996; Vuong et al, 1996).

Cytology

We have not seen an example of adenoid cystic carcinoma of the uterine cervix. Bittencourt et al (1979) from Brazil reported six such tumors and described the cytologic findings. Several additional case reports can be found in more recent literature (Dayton et al, 1990; Ravinsky et al, 1996; Vuong et al, 1996). The smears contained **sheets of small, fairly uniform cells**. In fortuitous cases, **central spaces with the characteristic hyaline deposits could be observed**. These cytologic findings are identical with tumors of the same histologic type observed in the salivary glands, trachea, or bronchus. In smears of cervix, **malignant cells of squamous type may accompany or even conceal the presence of adenoid cystic carcinoma**, which may be an incidental finding in biopsies.

Adenoid Basal Cell Carcinoma (Epithelioma)

This unusual low-grade tumor is usually discovered as an **incidental finding** in conization or hysterectomy specimens of **elderly women**, obtained because of cervical smears, usually showing a high grade squamous intraepithelial lesion or squamous carcinoma (Peterson and Neumann, 1995; Powers et al, 1996). The lesion was apparently first described by Baggish and Woodruff (1971) and by Daroca and Durandhar (1980). The lesion is composed of nests of **small basaloid cells surrounding small cystic spaces**, thus has some similarity to adenoid cystic carcinoma (Ferry and Scully, 1988; Grayson et al, 1999). However, the lesion is usually limited in size and does not spread through the cervix as observed in adenoid cystic carcinoma (Fig. 17-12). Brainard and Hart (1998) emphasized the essentially benign nature of the lesion

and suggested that the term “**epithelioma**” be used to describe it, thus preventing unnecessary treatment.

Cviko et al (2000) hypothesized that the lesion is a peculiar form of basal cell differentiation of squamous carcinoma with good prognosis. HPV type 16 was observed in the squamous components in several cases (Jones et al, 1997; Grayson et al, 1997).

Cytology

The diagnosis of adenoid basal cell carcinoma is usually an incidental finding in patients with cytologic diagnosis of a squamous intraepithelial lesion (SIL). Powers et al (1996) observed clusters of small epithelial cells on **retrospective** review of abnormal smears in three such patients. These authors concluded that the cytologic diagnosis of adenoid basal carcinoma could not be established. The smear pattern in 11 of 12 patients studied by Brainard and Hart (1998) was that of a high-grade SIL that led to the discovery of the lesion. It may be concluded that it is **virtually impossible to recognize this tumor type in cervicovaginal smears**.

Primary Mammary Carcinoma of the Vulva

Primary mammary carcinomas may occur along the anlage of the mammary glands, **the linea lacta**, which stretches from the axilla to the vulva. On the rarest occasion, mammary carcinoma may be observed in the vulva (Cho et al, 1985). Such tumors may be diagnosed by aspiration biopsy. Metastatic mammary cancer must always be ruled out. Another point of differential diagnosis is **carcinoma of sweat glands** that may occur in the vulva and may mimic mammary carcinoma to perfection. For description of cytologic features of mammary carcinoma, see Chapter 29.

Transitional and Squamotransitional Carcinomas of the Cervix

These very uncommon and poorly defined tumors are most likely variants of squamous cancer that may occur within the cervix and the endometrium. Lininger et al (1998) reported the presence of HPV type 16 in some of these neoplasms. There are no reported cases of cytologic presentation of these tumors.

Malignant Melanoma

General Data and Histology

Primary malignant melanomas are most **common in the vulva** (Chung et al, 1975; Ariel, 1981; Bradgate et al, 1990), **less frequent in the vagina** (summary in Gupta et al, 2002), and **exceedingly rare in the uterine cervix** (summary in Deshpande et al, 2001). These highly malignant tumors are usually capable of **pigment formation**, although the nonpigment-producing variety may also be observed. The tumors originate in embryologically-derived neuroepithelial cells that are incorporated into the epidermis of the skin and other epithelia. The configuration of malignant melanomas is often similar to tumors of epithelial origin in the form of solid sheets of cancer cells. Hence, the **differential diagnosis between a melanoma and a carcinoma is, at times, very difficult in the absence of pigment**. A very rare, benign condition, **melanosis of vagina**, may clinically mimic a malignant melanoma (Karney et al, 2001).

Histologic variants of melanoma, such as balloon cell melanoma, spindle cell, or sarcomatoid melanoma, are discussed in Chapter 34. In histologic sections from the female genital tract, so-

called **junctional changes** may sometimes be observed, although they are less common than in melanomas of the skin. When present, clear, large cells of melanoma are found singly and in clusters at the junction of the epithelium and subepithelial connective tissue (Fig. 17-13A). These findings are usually diagnostic of malignant melanoma in histologic material, but are rarely reflected in cytologic preparations.

P.542

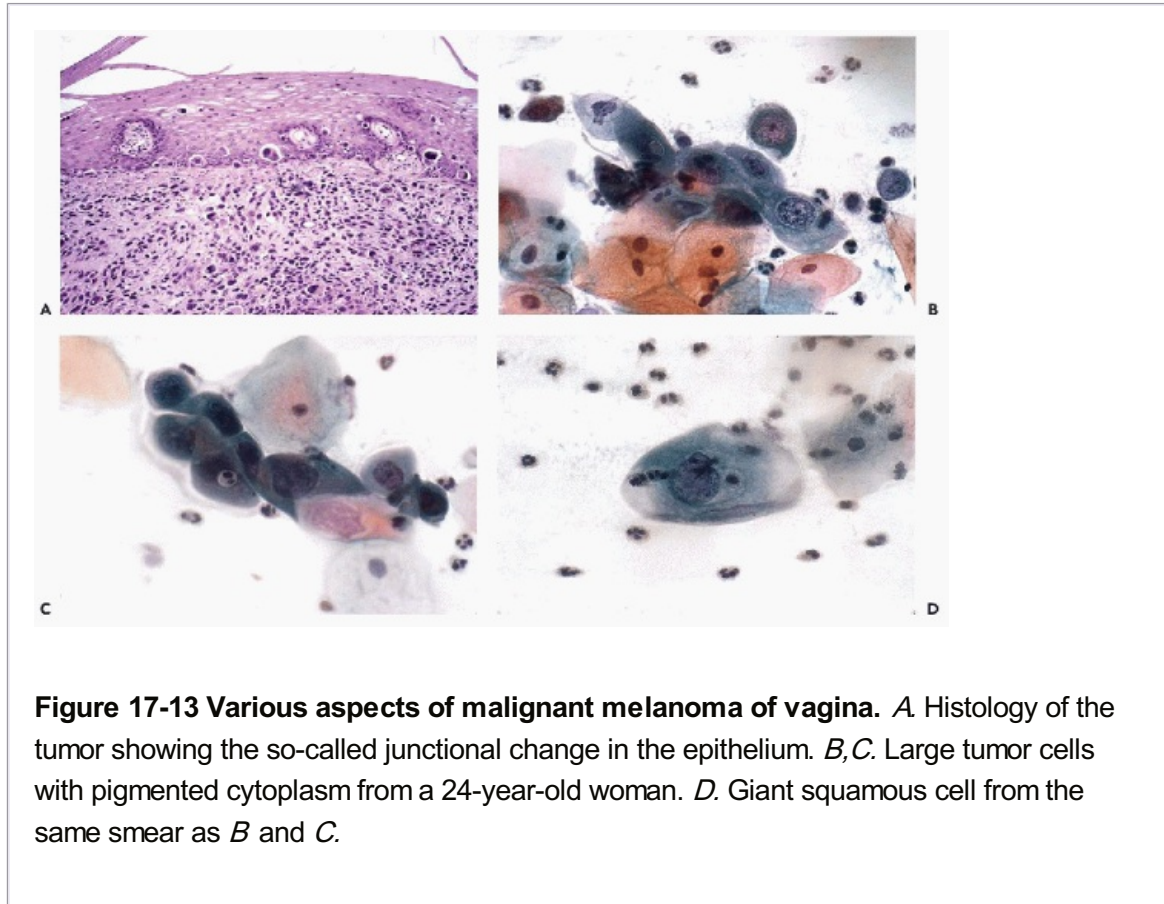

Figure 17-13 Various aspects of malignant melanoma of vagina. *A*. Histology of the tumor showing the so-called junctional change in the epithelium. *B, C*. Large tumor cells with pigmented cytoplasm from a 24-year-old woman. *D*. Giant squamous cell from the same smear as *B* and *C*.

Cytology

Cytologic presentation of primary malignant melanoma is similar for all organs of the female genital tract. The tumors can mimic almost any form and type of a malignant tumor. Most often, the tumors shed **large malignant cancer cells**, with abundant cytoplasm, **large hyperchromatic nuclei**, and **sometimes very large, prominent nucleoli** (Figs. 17-13 and 17-14). The presence of **intracytoplasmic granules of brown melanin pigment** usually clinches the diagnosis (see Fig. 17-13B,C). A frequent cytologic finding in melanomas of the vagina or cervix is the presence of **multinucleated cancer cells containing two or three, rarely more, peripherally placed large nuclei with large, often multiple nucleoli** (Fig. 17-14B). Occasionally, **intranuclear cytoplasmic inclusions (intranuclear vacuoles)** or “holes” may be noted (Hajdu and Hajdu, 1976). Intranuclear cytoplasmic inclusions and intracytoplasmic pigment deposits were observed in cancer cells in a cervical smear from a case of primary melanoma of the cervix reported by Fleming and Main (1994). For further discussion of intranuclear cytoplasmic inclusions in malignant melanomas, see Chapter 34. In the case shown in Figure 17-14, cells of an amelanotic malignant melanoma, and the original biopsy of the cervix, were interpreted initially as a poorly differentiated carcinoma. At autopsy, melanin pigment was documented in liver metastases.

It is of interest that, in the presence of melanoma, **abnormalities of squamous cells may be observed in vaginal smears. Most striking is the presence of very large squamous cells with abnormal nuclei** (Fig. 17-13D), or of pigment-bearing benign squamous cells. Such cells may signal the presence of disseminated melanoma elsewhere. The exact site of origin of such cells has not been determined, but their origin in the squamous epithelium of the vagina or cervix seems highly probable.

A few additional case reports of the cytologic presentation of primary malignant melanomas of the uterine cervix are on record (Mudge et al, 1981; Yu and Ketabchi, 1987; Holmquist and Torres, 1988). In the case of Holmquist and Torres, **spindle-shaped malignant cells were observed and initially interpreted as leiomyosarcoma**; the primary tumor involving the cervix and the vagina was a spindle-cell melanoma. A primary **malignant melanoma of the vulva** was diagnosed cytologically by Ehrmann et al (1962). Most lesions of this type are large and ulcerated when seen by the physician. The best hope for prophylaxis is a surgical excision of every pigmented lesion of the vulva.

Benign, melanin-containing **blue nevi**, which occasionally occur in the stroma of the uterine cervix (Goldman and Friedman, 1967; Jiji, 1971; Kudo et al, 1983), are not known to shed any abnormal cells in cervical smears.

P.543

Figure 17-14 Primary melanoma of the uterine cervix, initially mistaken for an anaplastic carcinoma. *A.* A small cluster of large tumor cells with prominent hyperchromatic nuclei shown at high magnification. *B.* A multinucleated tumor cell showing the peripheral arrangement of the large nuclei, provided with large nucleoli. There was no evidence of pigment in this smear. *C.* Original biopsy of the cervix showing a subepithelial malignant tumor composed of small cells. There was no evidence of junctional changes or of melanin formation and the patient was treated for carcinoma. *D.* The patient died of her tumor 2 years after the original smear and biopsy and melanin formation was clearly evident in the liver metastasis.

UNUSUAL MALIGNANT TUMORS IN INFANTS AND CHILDREN

Endodermal Sinus Tumor

These rare tumors occur primarily in the ovary but also occasionally in the vagina or uterine cervix (Larry et al, 1985; Kohorn et al, 1985). Ishi et al (1998) described the cytologic features of one such tumor in a 10-year-old girl with high serum levels of alpha fetoprotein.

Cytoplasmic hyaline inclusions were observed in the cytoplasm of tumor cells. For further discussion of this tumor, see Chapter 15.

Primitive Neuroectodermal Tumors

These very rare tumors have been described in the vagina and cervix (Horn et al, 1997; Pauwels et al, 2000; Karseladze et al, 2001). Ward et al (2000) described the cytologic findings in a vaginal tumor. Approximately **spherical monotonous tumor cells** with large nuclei and scanty rim of cytoplasm corresponded to rosettes characterizing this neoplasm.

CYTOLOGY OF CANCERS METASTATIC TO THE FEMALE GENITAL TRACT

A great many malignant tumors may produce metastases to the uterus or the vagina. Occasionally, the metastases may involve or reach the surface of these organs and the cancer cells may be found in the cervicovaginal preparations. Some of the cancer cells may also find their way to the vagina through the fallopian tubes, the endometrial cavity, and the endocervical canal, as has been shown by Bhagavan and Weinberg in 1969. It has been stated that, in **metastatic carcinoma, the background of cervicovaginal smears is often free of necrotic material and debris** ("tumor diathesis") when compared with primary carcinomas. **This is correct in some, but not all, cases.** Inflammation, necrosis and blood may be observed in smears, particularly if metastatic cancer has formed a large lesion with a necrotic surface. **Knowledge of clinical history** is usually helpful in assessing the cytologic findings. Still, the history of a treated or co-existing malignant tumor outside of the female genital tract does not rule out a second primary tumor within the genital tract. For example, the association of mammary carcinoma with synchronous

P.544

or metachronous carcinomas of the uterine cervix, endometrium, and ovaries is not uncommon.

Figure 17-15 Metastatic endometrial carcinoma in the vagina of a 65-year-old woman. A,B. Two aspects of the same smear showing clusters of small malignant cells with somewhat enlarged hyperchromatic nuclei. In the absence of history of prior endometrial carcinoma, the precise diagnosis could not be established.

Even if accurate clinical history is available, the correct cytologic recognition of a metastatic tumor, and its organ of origin, is not necessarily easy, and it is based largely on experience. In many instances, the diagnosis of metastatic cancer may be suspected, because the exfoliated malignant cells do not quite resemble any of the known patterns of cancer of the female genital tract. This is, admittedly, an area in which cytologic diagnosis falls into the realm of art, rather than science, but this is occasionally true of the histologic diagnosis of cancer as well.

Figure 17-16 Choriocarcinoma metastatic to cervix in a 20-year-old woman. *A,B.* Two aspects of the cervical smear showing very large cancer cells with hyperchromatic nuclei. *C.* Cervical biopsy from the same case showing metastatic choriocarcinoma to the uterine cervix. *D.* Another case of choriocarcinoma with the cervical smear showing numerous, very large cancer cells. (*A-C* case courtesy Dr. John Lukeman, M.D. Anderson Cancer Center, Houston, TX.)

P.545

Metastases From Other Component Organs of the Female Genital Tract

Cancers primary in one organ of the female genital tract may metastasize to another organ. For example, metastases of ovarian or endometrial carcinoma to the vagina are not uncommon (Fig. 17-15). The cytologic presentation is often similar to that of the primary tumors (see Chaps. 13 and 14).

Choriocarcinoma

Choriocarcinoma, a tumor of **trophoblasts from the chorionic villi** of the placenta, must be mentioned briefly. The tumors may be a consequence of pregnancy (**gestational choriocarcinoma**) or may be derived from **germ cells of the ovary or testis** (review in Berkowitz and Goldstein, 1996). The gestational choriocarcinomas are relatively uncommon in the Western world, but are exceedingly frequent in Asia, parts of Africa, and Latin America. Many of the tumors are preceded by an important abnormality of placental villi, the

hydatidiform mole, characterized by a grape-like swelling of the villi, visible to the naked eye. The hydatidiform moles can be **complete** (diploid) or **incomplete** (triploid). Only the complete moles are capable of progression to choriocarcinoma. Follow-up of these tumors is based on serum levels of **human chorionic gonadotrophins (hCG)**. Fully **malignant choriocarcinoma** may **metastasize extensively**, sometimes to the uterine cervix.

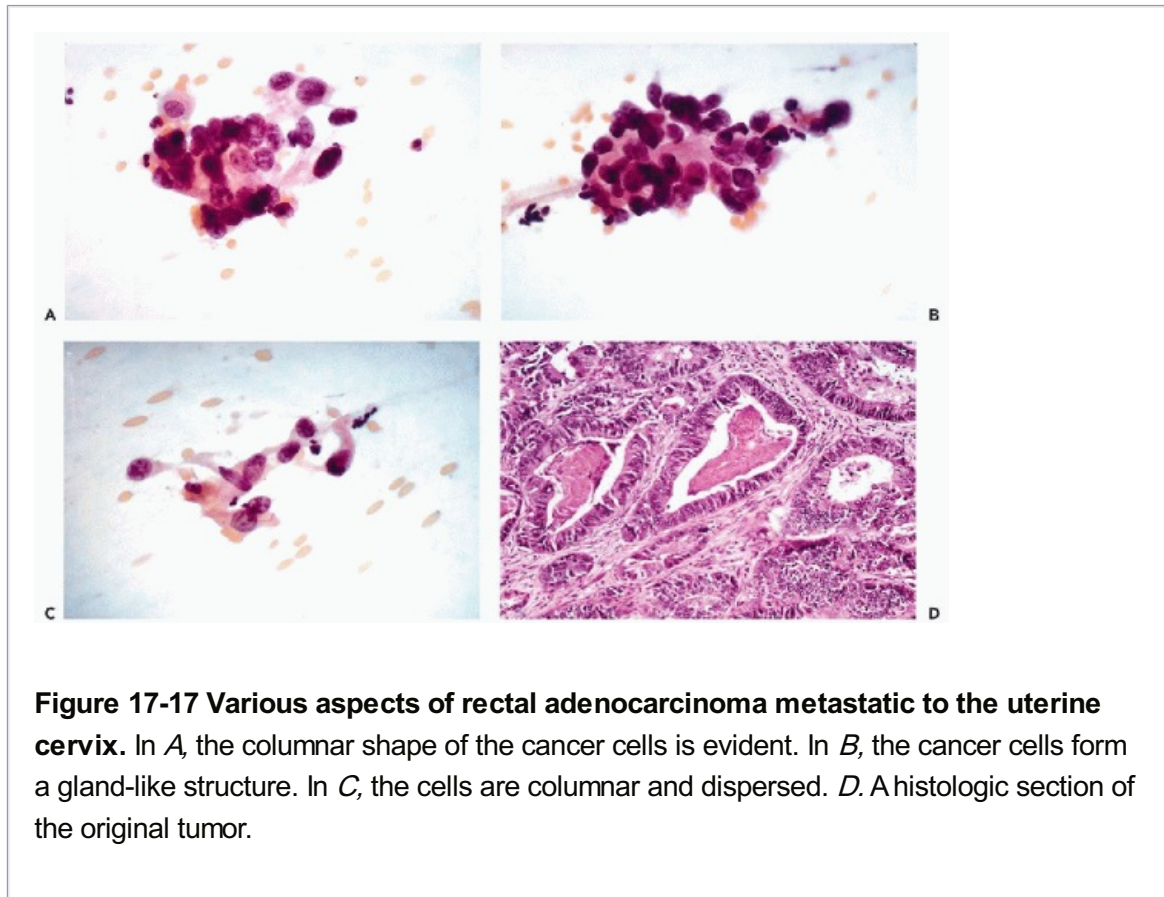

Figure 17-17 Various aspects of rectal adenocarcinoma metastatic to the uterine cervix. In *A*, the columnar shape of the cancer cells is evident. In *B*, the cancer cells form a gland-like structure. In *C*, the cells are columnar and dispersed. *D*. A histologic section of the original tumor.

Cytology

In the rare cases of metastatic choriocarcinoma to the lower genital tract, one can sometimes observe the component cells of choriocarcinoma that reflect **the two families of trophoblasts, the small cytotrophoblasts and the very large, multinucleated syncytiotrophoblasts**.

The innocent-appearing, small cytotrophic cells may be overlooked but syncytiotrophic cells are striking. The similarity of the large, multinucleated syncytiotrophic tumor cells to benign syncytiophoblasts must be noted (see Chapter 8). In most cases, however, only large cancer cells with single nuclei may be observed (Fig. 17-16). Because of the excellent response of these tumors to chemotherapy, the accurate recognition of the cytologic pattern may be of vital importance to the patient. History of recent pregnancy and high levels of human chorionic gonadotropin are helpful in diagnosis.

The possibility of early diagnosis of these tumors by cytologic techniques should be considered in those geographic areas of the world where the tumor is frequent.

Metastases From Adjacent Organs

Carcinomas of the colon and rectum are relatively frequent invaders of the female genital tract. Young and Hart (1998)

pointed out that metastatic cancers from the intestinal tract may mimic primary carcinomas of the ovary. A well-known manifestation of metastatic gastrointestinal cancer to the ovary is the **Krukenberg tumor** in which signet ring cancer cells are mixed with a spindle cell reaction in the ovarian stroma. Clinical complaints referable to the genital tract may be the first evidence of disease. In rare cases, the diagnosis of colonic cancer may be first established in cervicovaginal smears.

Figure 17-18 Colonic carcinoma, first diagnosed in cervical smears in a 68-year-old woman. *A.* A cluster of columnar cancer cells. *B.* A cluster of benign endocervical cells next to a cluster of tumor cells, some of which show cytoplasm distended with mucus. *C.* Histologic section of colonic carcinoma invading the uterine cervix. *D.* Another example of metastatic colonic carcinoma. The cancer cells in the center of the field have a “signet ring” configuration (*arrow*).

The most common cytologic presentation of colorectal carcinoma is **cancer cells, occurring singly or in thick clusters, composed of large, often columnar cells** with finely stippled or vacuolated cytoplasm, suggestive of mucus production (Figs. 17-17 and 17-18). The columnar cells are sometimes arranged in **parallel, palisade-like clusters** or form **rosettes**. The **nuclei are large**, usually but not always hyperchromatic, often provided with **large nucleoli**. Less often, the cancer cells are of the **signet-ring type**, i.e., approximately **spherical, with a large hyperchromatic nucleus pushed to the periphery by a large cytoplasmic mucus vacuole** (Fig. 17-18D.)

The **differential diagnosis of colonic carcinoma** comprises primary **adenocarcinoma of the endocervix** and **vaginal adenocarcinoma**, the latter particularly in a young woman with a history of maternal exposure to diethylstilbestrol (DES) (see Chap. 14). The presence of **normal endocervical cells in the smear is in favor of metastatic colonic carcinoma** (Fig. 17-18B). Rarely, benign endocervical or endometrial cells with large mucus vacuoles and normal nuclei may mimic signet ring cells of colonic carcinoma.

Urothelial (transitional cell) carcinoma of the bladder may form metastases to the female genital tract. In the absence of clinical history, the finding of **large, multinucleated tumor**

cells with one sharply delineated surface (umbrella cells; see Chap. 22) may occasionally allow for a specific diagnosis. In most cases, however, there are no distinguishing cytologic features that may allow the exact identification of tumor type (Fig. 17-19). It is of note that **metastatic bladder cancer to the vagina or penis may result in changes similar to Paget's disease** (Koss, 1985) (Fig. 17-19D; see Chap. 23). For further comments on metastatic urothelial carcinoma in fluids, see Chapter 26.

Metastases From Distant Sites

Mammary carcinoma is by far the most common source of metastases to the female genital tract. The cytologic presentation is very variable. Occasionally, **cancer cells are arranged in "single file,"** suggestive of lobular carcinoma (Fig. 17-20A,B) but, more often, the smear contains clusters of malignant cells suggestive of adenocarcinoma without distinguishing features (Figs. 17-20C,D, 17-21). Metastatic mammary carcinoma, particularly of the **lobular type, may also have a signet ring cell pattern with a large vacuole occupying the center of the cell and the nucleus pushed to the periphery.** The **mammary signet ring cells are much smaller than the cells from tumors of the gastrointestinal tract** (see Chap. 29). As a further point of distinction, **a central condensation of mucus may be observed within the cytoplasmic vacuoles in mammary, but not the gastrointestinal cancer.** **Tamoxifen therapy** does not protect women from developing metastatic mammary cancer, as shown in Figure 17-21C,D. Metastatic mammary carcinoma to endometrial polyps caused by tamoxifen have been reported (Houghton et al, 2003). For further description of mammary cancer cells, see Chapter 29.

P.547

Figure 17-19 Metastatic urothelial carcinoma from the urinary bladder to vagina. A-C. Clusters of obvious malignant cells, some of which have columnar configuration. Note the sharply demarcated cytoplasm in some of the cells. **D.** Biopsy of vagina showing the pagetoid appearance of the epithelium.

Figure 17-20 Metastatic mammary carcinoma to the uterus. *A* A classical single-file arrangement of breast cancer cells consistent with lobular carcinoma, shown in *B*. *C*. Another aspect of metastatic mammary carcinoma in which the cells form a papillary cluster. *D*. Biopsy from same case as *C* showing metastatic mammary carcinoma to the cervix.

P.548

Cancers of a variety of other distant primary sites may occasionally form metastases to the female genital tract. We have observed **bronchogenic**, **pancreatic**, and **renal carcinomas**, to name only a few, although their exact identification is rarely possible in the absence of clinical history and prior histologic or cytologic material for purposes of comparison. Metastases from **gastric cancer** were described by Matsuura et al (1997), from a **salivary duct carcinoma** (Vinette-Leduc et al, 1999), and from a variety of sites by Gupta and Balsara (1999).

Metastatic melanoma to the vagina, an extremely uncommon event, may also occur (Chung et al, 1980; Gupta et al, 2003). Undoubtedly, other metastases will be described in the future but their cytologic features are not likely to be specific.

Figure 17-21 Metastatic mammary carcinoma in cervicovaginal smears. *A* Large, loosely structured clusters of relatively small malignant cells. The precise diagnosis of tumor type could not be established on morphology alone. *B*. Biopsy of cervix in this case showing a large area of metastatic mammary carcinoma in the uterine cervix. *C, D*. Metastatic mammary carcinoma in a 65-year-old woman receiving Tamoxifen therapy. *C*. A classical papillary cluster in the background of an atrophic smear. *D*. A smaller cluster of malignant cells in the same smear as *C*.

Malignant Lymphomas and Leukemias

Generalized non-Hodgkin's malignant lymphomas may involve the female genital tract with a frequency that is perhaps not sufficiently appreciated. They may mimic primary cancer of the cervix, and also of the vagina, the uterus, and the ovaries. The alert pathologist, regardless of whether he or she is dealing with a histologic or a cytologic preparation, may be in a position to render the correct diagnosis **by merely considering malignant lymphoma in the differential diagnosis.**

Large-cell malignant lymphomas are the most common

P.549

form of malignant lymphoma to invade the female genital tract. **Small-cell lymphomas and acute leukemias** are cytologically identical. The cytologic presentation is identical to primary tumors of this type, described above. In leukemias, there is often evidence of bleeding, and numerous erythrocytes may obscure the pattern of the smear. Ceelan and Sakurai (1962) reported cytologic evidence of leukemia in 17 of 61 consecutive leukemic patients from whom cervical smears were obtained. It has also been recorded by Kanter and Mercer (1950) that ulcerative lesions of the vagina may occur in **monocytic leukemia.**

Metastatic **Hodgkin's disease** may occasionally be observed in cervical smears. Uyeda et al (1969) described classic Reed-Sternberg cells with two "mirror-image" large nuclei and prominent nucleoli in a patient with this disorder.

Effects of Therapeutic Procedures on the Epithelia of the Female Genital Tract

HEAT, COLD, AND LASER TREATMENT

Heat, in the form of cautery, is an ancient remedy for local treatment of various lesions. In its more modern form, as the **electrocautery**, it has enjoyed great popularity in the treatment of various benign disorders of the female genital tract, such as chronic cervicitis. Large loop electrosurgical excision procedure (**LEEP**) of precancerous lesions of the cervix is another application of electrocautery. Other forms of locally destructive therapy include: cold, in the form of **cryosurgery**, and energy, transmitted in the form of a **laser** beam, used in the treatment of intraepithelial neoplastic lesions of the uterine cervix and of the vagina (see Chaps. 11 and 14). Because cytology, and particularly the cervicovaginal preparations, are extensively used as a follow-up measure after treatment, it is important to distinguish cell changes caused by therapy from evidence of recurrent cancer.

All these forms of therapy have in common cell changes that are of two types:

- **Initial changes**, caused by tissue and cell necrosis under the impact of treatment
- **Secondary changes**, caused by epithelial regeneration following the injury

Initial Changes

In principle, cervicovaginal samples should not be obtained for about 6 weeks following treatment. However, ever so often, smears are obtained sooner and the cell changes seen in such material are described here. Immediately after, and for about 7 days following treatment, **tissue and cell necrosis are** the predominant features observed in cytologic and histologic material (Fig. 18-1A). The necrosis is of the coagulative type and, hence, the affected epithelia

P.554

may retain their overall structure, even though their component cells may be severely injured.

Figure 18-1 Effects of cryosurgery and cautery. *A.* Overview of a smear obtained 6 weeks after cryosurgery for carcinoma of the cervix. Marked inflammation, distortion of squamous cells, and a few suspicious cells with hyperchromatic nuclei (*arrows*) are seen. *B.* Nuclear and cellular enlargement and nuclear haziness one week after cautery. *C.* Parabasal cells with basophilic cytoplasm and somewhat enlarged nuclei showing “repair” 2 weeks after cautery. *D.* Smear obtained 4 weeks after cautery showing markedly atypical metaplastic squamous cells. It is impossible to determine from this smear pattern whether or not this patient has been cured. Further follow-up is essential.

In **cervicovaginal smears**, the background usually contains cell debris and evidence of **acute inflammation in the form of polymorphonuclear leukocytes**. The resilient **squamous cells** may become **enlarged because of cytoplasmic vacuolization** but often **retain their cytoplasmic silhouette**. Their **nuclei are either “empty” or smudged**, without any internal structure, or show nuclear **pyknosis and karyorrhexis** (Fig. 18-1B). The more fragile **endocervical cells** may be **enlarged and vacuolated, sometimes misshapen**, with **opaque or fragmented nuclei**. For the most part, however, the endocervical cells rarely survive intact and usually are fragmented. Holmquist et al (1976) emphasized “distortion” or odd shapes of endocervical cells after carbon-dioxide laser treatment. Similar observations were reported after cryosurgery (Hasegawa et al, 1975).

Thomas (1997) described an unusual procedure in the form of **immediate post-LEEP endocervical brush to determine** the presence of residual disease or lesions located beyond the reach of the loop. The endocervical cells were often elongated and showed distortion of nuclear configuration with oddly shaped, often “smudgy” nuclei. Thomas (1997) stressed the difficulties in the interpretation of such smears, compounded by the presence of blood and necrosis. The value of this procedure has not been ascertained.

Secondary Changes

The secondary changes are more common because they may persist for several weeks, when most of the follow-up smears are obtained. Starting on or about 8 days after treatment, the smear background usually shows evidence of inflammation and sometimes persisting necrosis.

Lymphocytes and macrophages, the latter sometimes multinucleated, are the dominant inflammatory cells. In the epithelial cells, **cytoplasmic vacuolization** may persist for as long as 6 weeks after cautery and for several months after cryosurgery (Gondos et al, 1970). Another persisting change is **slight nuclear enlargement, hyperchromasia**, and the appearance of **nuclear “folds” or lines**. Within 1 week after treatment, **sheets of parabasal squamous cells** of various sizes, with well-preserved, dark nuclei with stippled chromatin granules and basophilic cytoplasm, may be observed, signaling the beginning of regeneration or “repair” of the squamous epithelium (Fig. 18-1C). Sheets of **smooth muscle**

P.555

cells may be observed in **endocervical brush samples**, particularly if the sampling was obtained before epithelial regeneration has been completed or if the brushing was very vigorous.

In somewhat later stages of epithelial regeneration, cell changes of **florid squamous metaplasia or “repair,”** as described in detail in Chapter 10, may be noted. Sheets or clusters of **parabasal squamous cells with basophilic cytoplasm and relatively large, often granular nuclei with prominent, large nucleoli** may be observed. Nucleolar prominence has been emphasized by Hasegawa et al (1975) in patients after cryosurgery. **Mitotic figures** can occur in such epithelial fragments. These changes may persist for about six weeks after treatment.

The duration of the therapy-induced cell changes is variable and depends on the anatomic extent and mode of treatment. The procedures used are not standardized and, consequently, significant differences occur among practitioners and institutions. If the treatment is confined to a small area of the cervix, its effects will be less noticeable and of shorter duration than if much of the epithelium of the exo- and endocervix has been treated or removed together with the underlying connective tissue and muscle.

The most important practical point is the **determination of whether intraepithelial neoplasia has been destroyed by treatment. In our experience, the diagnosis of residual disease should not be made until at least six weeks have elapsed after treatment**, or until complete healing of the therapy-induced changes has taken place. **Prior to that time, cancer cells derived from the original, adequately treated lesion may still occur in smears, even in patients with a favorable response. Past the 6 week deadline**, the presence of cancer or dyskaryotic (dysplastic) cells may be interpreted in the customary fashion, described in previous chapters, and their presence indicates **persisting disease**. However, the post-treatment cytologic examination to detect persisting lesions is not fully reliable and has its difficulties and failures. An example of this problem is shown in Figure 18-1D wherein the differentiation between atypical repair and recurrent lesion proved to be difficult until further smears revealed a low-grade squamous intraepithelial lesion (LGSIL). Thus, it is advisable to combine the cytologic follow-up with colposcopy and testing for high-risk human papillomavirus (HPV). Chua and Hjerpe (1997) reported that the **presence of high risk human papillomavirus**, determined by PCR, was an important indicator of recurrent high-grade precancerous lesions. There is no information on the value of this procedure in patients treated by laser or cryotherapy.

TOPICAL ANTIBIOTICS

A topical application of broad-spectrum antibiotics may result in **massive desquamation of the squamous epithelium** of the cervix and the vagina, as discussed in Chapter 11.

Sometimes cancer cells may be concealed by sheets of benign epithelial cells. In some cases of carcinoma in situ, we have observed sloughing of the cancerous epithelium, with resulting disappearance of the lesion. Before pronouncing an in situ carcinoma as “cured” by this method, it is essential to follow the patient for at least 3 years, since cancer cells may reappear in smears at a time when least expected. It would not be wise to rely on this chance action of antibiotics for treatment of precancerous lesions. These observations are reported here as a matter of scientific interest only.

RADIOTHERAPY

Nearly all of the information on the effects of radiotherapy on the organs of the female genital tract, be it as **external irradiation, radium** or implanted **radioactive seeds**, pertains to treatment of **carcinoma of the uterine cervix or vagina**. Although the changes in the benign epithelia of the female genital tract are the same for all forms of radiotherapy and all tumors, regardless of location, the changes observed in cancer cells are limited to cervical carcinoma, because there is very little reliable information on cancers in other component organs of the female genital tract. The effects of radiotherapy may be described as acute and chronic.

Acute Effect on Benign Epithelia

Graham (1947) studied extensively the immediate effect of radiation on benign **squamous epithelium** of the cervix and the vagina. She noted and described the following cellular changes:

- **Marked cellular enlargement accompanied by a proportional nuclear enlargement**
- **A peculiar “wrinkling” of the nuclei**
- **Vacuolization of the cytoplasm or, occasionally, of the nucleus**
- **Multinucleation**
- **Appearance of bizarre cell forms**

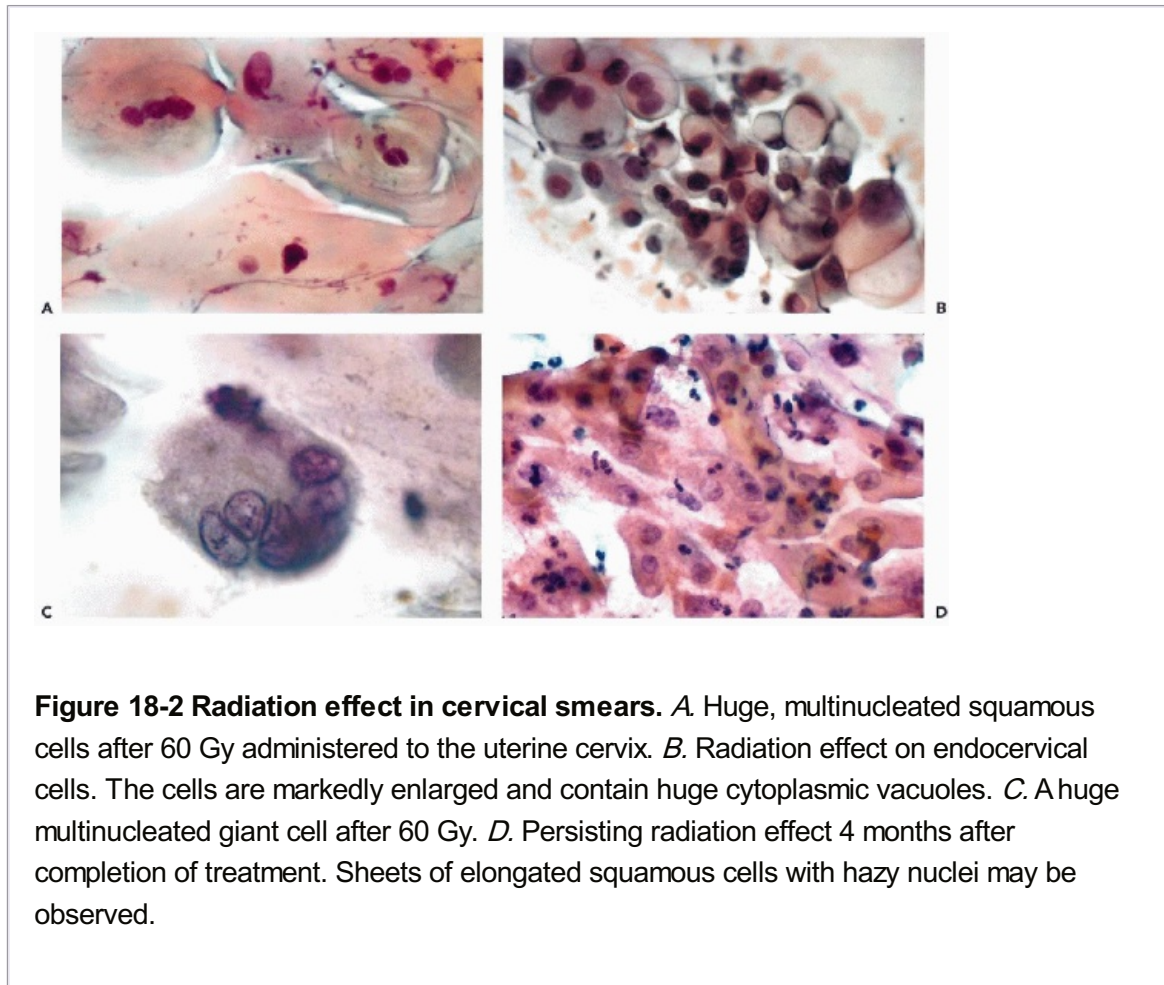

The changes represent the damaging effect of radiation on individual cells and various stages of cell death (Fig. 18-2A). The most striking change in such smears is **generalized cellular enlargement**, usually affecting the cytoplasm and the nucleus, **without a change in the nucleocytoplasmic ratio. For the most part, the enlarged nuclei are homogeneous and pale, easily recognized as benign. The “wrinkling” of the nucleus**, described by Graham, **occurs rather rarely. Unfortunately, in squamous cells**, radiation may also produce **nuclear hyperchromasia, multinucleation, and bizarre forms** (Fig. 18-2C) and may render the differential diagnosis from cancer cells very difficult.

The **endocervical cells** are well preserved, but there is a **marked vacuolization and enlargement of both the cytoplasm and the nucleus** (Fig. 18-2B). Within the nucleus, **granules of chromatin** stand out against the pale background. Corresponding changes may be noted in histologic sections. **Bizarre nuclear abnormalities**, common in squamous cells, are **less frequent in endocervical cells**. Similar observations were reported by Little (1968), Boschann (1981), and Shield et al (1992).

The acute changes in the squamous and endocervical cells usually recede a few weeks after completion of radiotherapy

in favor of the chronic changes, described below. In some patients, however, **these**

changes may persist for several months after completion of radiation therapy.

Persistent Effect on Benign Epithelia

In some patients who have undergone radiation therapy to the pelvic area, there may be persistence of radiation effect upon the **benign squamous** and the **endocervical epithelia**, stretching over a **period of many years**. We have observed such changes 28 years after the completion of radiotherapy. The biologic phenomena that account for this effect are unknown. It may be speculated that, in susceptible patients, the genetic make-up of the irradiated epithelium has been altered. The occurrence of **post-radiation carcinoma in situ** (see below) and of **cancer in organs within the field of radiation** support this hypothesis. Neither the amount of radiation nor the manner of application appears to play a role; it is rather a matter of individual response to radiation injury.

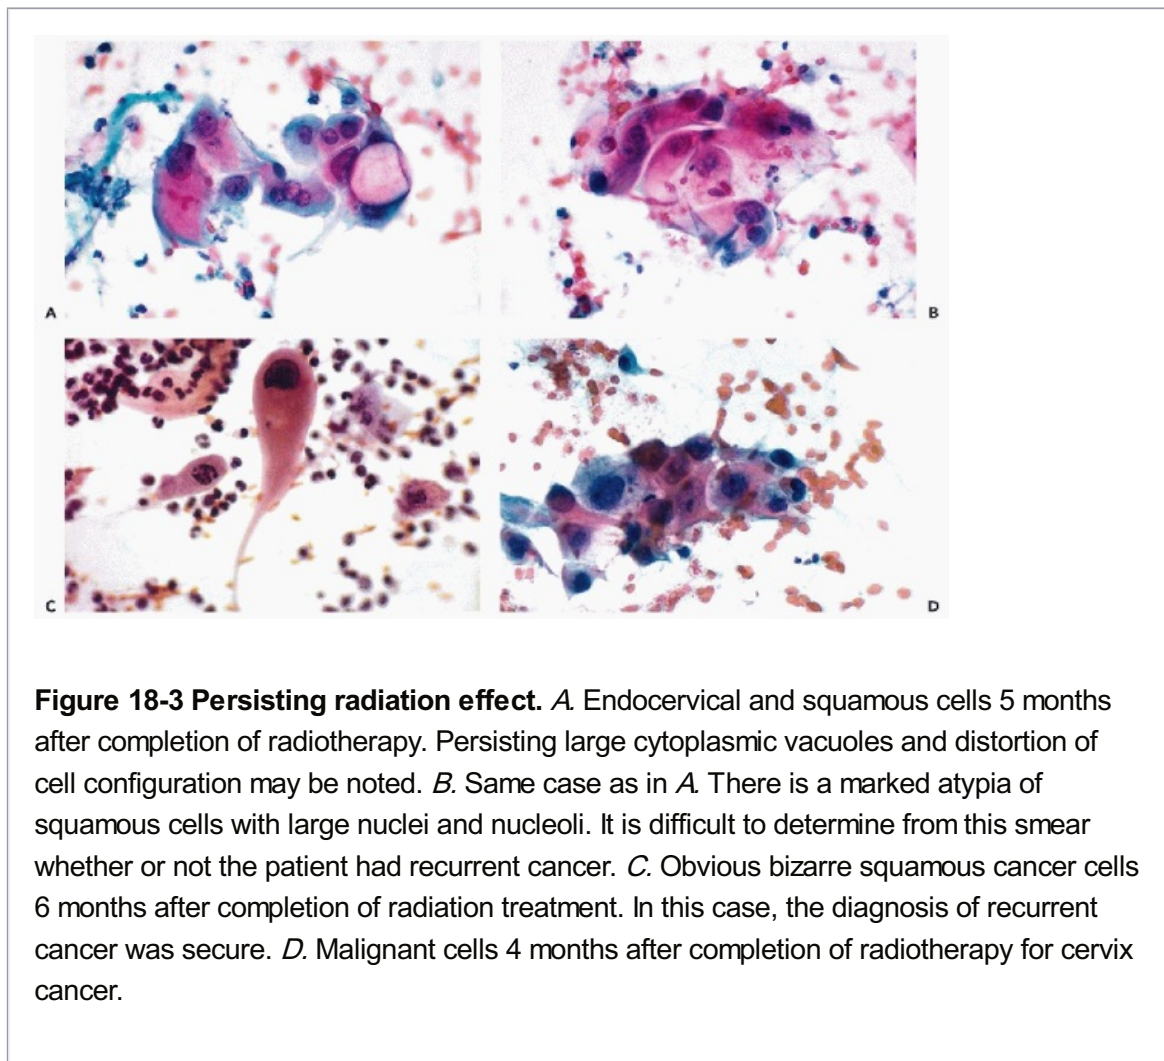

The cytologic manifestations of a late radiation effect differ from the acute radiation effect. The phenomena of acute injury to the cell, such as nuclear and cytoplasmic vacuolization and nuclear necrosis are absent. Commonly, there still is a persisting **slight enlargement of cells and their nuclei**. The **squamous cells often desquamate in cohesive sheets of elongated cells, sometimes mimicking smooth muscle cells, with elongation of the rather homogeneous nuclei** (Fig. 18-2D). Among the elongated nuclei, a few are often hyperchromatic. Multinucleation is less frequent than in the acute radiation response. The **nuclei of endocervical cells** may also show **persisting enlargement and some hyperchromasia** (Fig. 18-3A). The changes are sufficiently characteristic for an experienced and knowledgeable observer to diagnose late radiation effects in cervicovaginal smears.

Effect on Cancer Cells

During radiotherapy, the cancer cells, regardless of type, undergo essentially the same changes as the benign epithelial cells, that is, **cellular and nuclear ballooning and extensive vacuolization of both the cytoplasm and the nucleus**. Occasionally, extensive fragmentation of the nuclei may be observed, most likely a form of cell death or **apoptosis** (see Chap. 6). Squamous cancer cells usually retain some of their cytoplasmic characteristics and can be recognized; however, poorly differentiated cancer cells and cells of adenocarcinomas usually cannot be specifically classified. Marked radiation

P.557

effect may enhance or obliterate some of the features of malignant cells, such as abnormal structure of the nuclear chromatin and the presence of large nucleoli (Fig. 18-3B). However, **some measure of hyperchromasia usually persists, as does an abnormal nucleocytoplasmic ratio**.

Differential Diagnosis Between Radiated Benign and Malignant Cells

The question of differentiation between irradiated benign and malignant cells is of academic interest only. **If the malignant cells display radiation effect** that obliterates their characteristic features, they are not capable of reproduction; therefore, they **provide no information on the presence or the absence of viable tumor**. **Only those cancer cells that are either unaffected or only slightly affected by radiation are of concern in the**

diagnosis of persistent or recurrent tumor.

In reference to cancer of the uterine cervix, **persistence of unaffected cancer cells in smears during and after treatment suggests that a tumor is not responding to radiation.** However, as reported by Zimmer (1959), cancer cells may persist for as long as 3 weeks after completion of treatment, and yet the patients appeared to be cured and did not show tumor recurrence for several years. Such cases are exceptional. It must be stressed that, in spite of apparent favorable cytologic response of the tumor to treatment, the tumor may persist within the subepithelial stroma or other areas not accessible to cytologic sampling. In such situations, the absence of cytologic evidence of persisting carcinoma is of no clinical value whatever.

Recurrent cancer of the uterine cervix, after successful initial treatment, may be recognized in cervicovaginal smears and its manifestations are identical to those of primary cancer, sometimes in the background of smears showing slight persisting radiation effect (Fig. 18-3C,D).

Postradiation Carcinoma In Situ in the Cervix and Vagina (Post-Irradiation Dysplasia)

In 1961, we reported on a group of patients who, after a disease-free time interval ranging from 1.5 to 17 years **following successful radiotherapy for invasive squamous cancer** of the cervix, developed **cytologic abnormalities consistent with carcinoma in situ or closely**

P.558

related forms of cervical intraepithelial neoplasia. The term “**post-irradiation carcinoma in situ**” was proposed by Koss et al (1961). The term “**postradiation dysplasia**” was subsequently used by Patten et al (1963) in describing this lesion. The abnormal epithelium, located on either the irradiated cervix or vagina, **often could not be visualized** on inspection or colposcopy and was exceedingly difficult to localize within the scarred genital tract. In some cases, numerous biopsies of the cervix and the vaginal mucosa were required to confirm the presence of **postradiation carcinoma in situ** (Fig. 18-4). In one of the patients of the original series who was treated by hysterectomy for the postradiation carcinoma in situ, there was associated residual metastatic carcinoma in an obturator lymph node that would not have been discovered and removed were it not for the vaginal lesion. It is of note that Fujimura et al (1991), Holloway et al (1991), and Longatto Filho et al (1997) observed the **presence of human papillomavirus (HPV)** in cervicovaginal smears of 18 women after completion of radiotherapy for invasive cancer of the uterine cervix. Holloway et al (1991) observed HPV type 16 in cancer of the cervix recurring after therapy.

Figure 18-4 Postradiation carcinoma in situ (dysplasia). *A.* The original pattern of invasive squamous carcinoma treated by radiotherapy in 1946. *B.* Cervical smear obtained 13 years later (in 1959) showing large dyskaryotic (dysplastic) cells with markedly enlarged nuclei. *C.* Classical carcinoma in situ in a biopsy obtained in 1959. *D.* Another example of postradiation carcinoma in situ. The smear shows large granular nuclei with prominent nucleoli and mitoses.

Subsequently, in a number of personally observed cases, the ominous significance of these lesions became apparent. **Several patients, with postradiation carcinoma in situ (or dysplasia) who were followed conservatively, developed invasive carcinomas of the cervix or of the vagina,** sometimes after many years of follow-up. In yet other patients, disseminated metastatic carcinoma developed within a short period of time (Figs. 18-5 and 18-6).

The cytologic presentation of these lesions failed as a means of prognostication. Some cases with a cytologic presentation akin to classic squamous carcinoma required many years to progress to invasive carcinoma (see Fig. 18-6); others, with a cytologic presentation dominated by dyskaryotic

P.559

(dysplastic) superficial and intermediate squamous cells, hence resembling a low-grade lesion, were followed by rapid progression and dissemination of the tumor (Fig. 18-5).

Figure 18-5 Postradiation carcinoma of cervix. *A.* The original squamous cancer treated by radiotherapy in 1958. *B.* Smear obtained in 1975 showing markedly abnormal cells corresponding to an intraepithelial neoplastic lesion. Several of the cells resemble koilocytes, suggestive of HPV infection. *C.* Another field of the smear shown in *B.* *D.* Squamous carcinoma in the left external iliac node observed in 1975, after the smear shown in *B* and *C*.

Patten et al (1963) reported on a group of 28 patients with similar cytologic and histologic patterns, and elected to call the lesion “**post-irradiation dysplasia.**” One of his patients developed invasive squamous carcinoma after 19 months of follow-up. Wentz and Reagan (1970) subsequently reported on 84 patients with “post-irradiation dysplasia.” Seventy-one of these patients developed the lesion within 3 years or less after completion of radiotherapy for invasive carcinoma of the cervix, whereas 13 patients developed the lesion 3 to 12 years after completion of therapy. Forty-seven (56%) of the 84 patients developed recurrent carcinoma and the majority of them died of disease. **The probability of developing recurrent cancer was much higher for patients who developed the post-irradiation change within 3 years or less than for the patients with a delayed onset.** The overall 5-year survival rate for the 84 patients was only 44%, although most of them initially had carcinomas of stage I (30 patients) and stage II (44 patients), wherein a much better survival rate could be expected for these stages of disease. This study fully confirmed the **serious prognostic significance of the post-irradiation intraepithelial lesion, regardless of the name attached to it.**

Okagaki et al (1974) studied 60 patients who received radiotherapy for carcinoma of the cervix of various stages. Twenty-three patients (38.5%) showed evidence of postirradiation lesions. The study of **DNA content of the abnormal cells** by destaining the slides and re-staining with Feulgen stain showed diploid, polypoid, or aneuploid patterns. Twenty-seven of the 60 patients died; 13 of these had “post-irradiation dysplasias,” 6 of which were aneuploid. Two of the 33 surviving patients also had aneuploid dysplasia. The conclusions of this paper, suggesting that **DNA measurements are of prognostic value**, have been confirmed by Davey et al (1992, 1998).

Regardless of the controversy over the name of the cytologic and histologic lesions observed

following completion of radiotherapy for invasive cancer of the uterine cervix, it may be unequivocally stated that the presence of **post-irradiation intraepithelial neoplasia** carries with it a **very serious prognostic connotation**. The majority of these patients will die of invasive and metastatic carcinoma, unless rapidly treated.

The use of periodic cytologic examinations is mandatory following irradiation treatment of cervical cancer to detect local recurrences promptly and to treat them without delay. The early identification of post-irradiation intraepithelial neoplasia should lead to vigorous treatment of patients at risk.

P.560

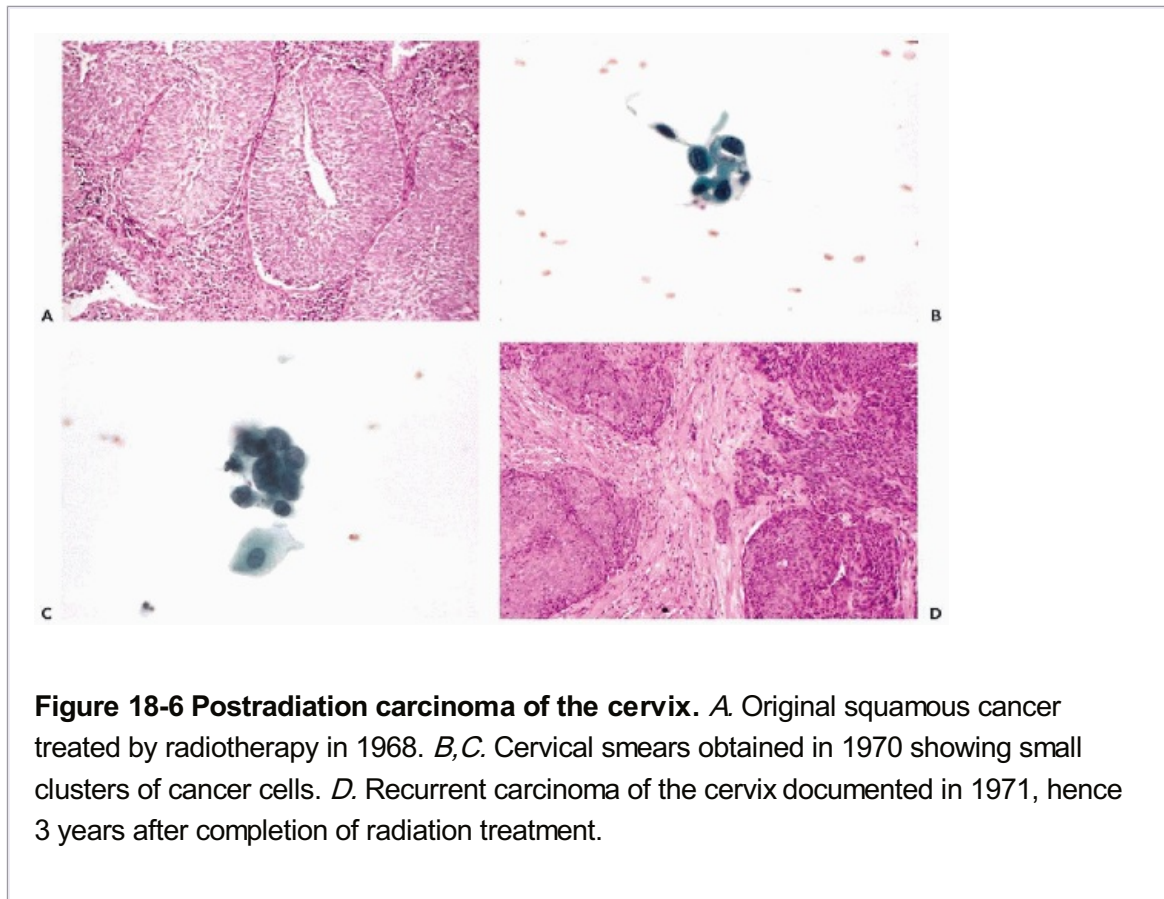

Figure 18-6 Postradiation carcinoma of the cervix. *A.* Original squamous cancer treated by radiotherapy in 1968. *B,C.* Cervical smears obtained in 1970 showing small clusters of cancer cells. *D.* Recurrent carcinoma of the cervix documented in 1971, hence 3 years after completion of radiation treatment.

Postradiation Cancers of Other Pelvic Organs

A successful radiotherapeutic eradication of a primary cancer of the cervix or endometrium puts the surviving patient at risk for the development of other cancers within the radiation field. An **excess of leiomyosarcomas and endometrial carcinomas** has been observed in such patients (Smith and Bowden, 1948; Meredith et al, 1986). Carcinomas of the bladder and rectum may also occur (Fehr and Prem, 1974; Kapp et al, 1982; Russo et al, 1997). **Soft tissues and pelvic bone are also at risk and sarcomas may develop in these organs.** It is empirically assumed that **at least 6 years must elapse** between the conclusion of radiotherapy and the development of the new cancers within the irradiated area **for the tumors to be classified as radiation related**. It is of note that some of the radiation-related cancers, notably of the uterus, may be diagnosed in cervicovaginal smears (Meredith, 1986). We have identified **several endometrial carcinomas in vaginal smears in patients previously irradiated for a variety of diseases, including endometrial hyperplasia** (see Chap. 13).

Other Complications of Therapy for Cancer of the Cervix

Chlamydia Trachomatis and Herpesvirus

Several observers reported the presence of *chlamydia trachomatis* and *herpesvirus* in patients treated for cancer of the uterine cervix (Longatto Filho et al, 1990, 1991; Maeda et al, 1990). The cytologic findings were identical with those described in Chapter 10.

Vaginal and Sexuality Changes

Hartman and Diddle (1972) observed vaginal stenosis after radiotherapy for cervix cancer. Bergmark et al (1999) reported that significant abnormalities of the vagina (shortening and atrophy) occurred in about 25% of women treated for cancer of the, regardless of mode of therapy. These changes, which interfered with sexual function, have not been correlated with cytologic findings but it may be hypothesized that they correspond to women with postradiation changes in benign epithelium, described earlier.

THE SEARCH FOR PROGNOSTIC FACTORS IN RADIOTHERAPY OF CERVICAL CANCER

The treatment of cervical cancer has undergone an almost cyclic evolution since the turn of the 20th century. The surgical treatment devised by the great pioneers, such as Wertheim and Schauta during the last years of the 19th century, gave way to radiation therapy early in the 20th century, followed by a revival of the surgical approach in

P.561

the 1960s. Currently, both the radiotherapy and surgical treatment have their advocates and their opponents.

It is obvious to all students of cervical cancer that the response of the tumor to adequate therapy is not always the same, in spite of apparently similar clinical presentation of the disease and similar manner of treatment. With the introduction of **molecular genetics**, it has been shown that the modification of certain genes governing control of the cell cycle, notably the retinoblastoma gene (Rb) and p53, or expression of the oncogene HER2-neu, may be associated with poor treatment results in some cancers (see Chap. 7). Very little is known about genetic factors influencing the results of treatment for invasive carcinoma of the uterine cervix (see Chap. 11). Attempts have been made in the years past to determine whether histologic, cytologic or cytogenetic observations, or ploidy of tumor DNA, may provide prognostic information. These efforts had only modest success in providing clinically relevant prognostic profiles.

Histology as a Prognostic Factor

Glücksman and Cherry (1956) attempted to correlate the changes in consecutive biopsies of the tumor with the **response to radiation therapy**. These investigators observed that **the well-differentiated squamous carcinomas respond to radiotherapy better than the less well-differentiated varieties**. Wentz and Reagan (1959) also correlated the histologic type of invasive cervix cancer with response to radiotherapy. The results were somewhat different from Glücksman's, inasmuch as the response to radiotherapy was best for the large-cell nonkeratinizing carcinoma, followed by keratinizing carcinoma. The response of the small cell cancer was poor.

Our own group (Sidhu et al, 1970) observed that the **results of surgical treatment of**

carcinoma, stage I, also depended on tumor type. Keratinizing carcinomas did poorly, but the **survival of patients with small cell cancer was surprisingly satisfactory.** We also noted that the presence of a **lymphoid infiltrate in the cervical stroma of the resected tumors was a favorable prognostic factor,** suggestive of a good immune response. Also, **patients older than 45 years of age at the time of diagnosis fared much better than younger patients.**

Cytology as a Prognostic Factor

The late Ruth and John Graham (1951, 1953, 1954, 1960) attempted to define the **biologic response of the patients to radiotherapy by changes in benign cells in cervicovaginal smears.** Thus, the **radiation response (RR)** was the percentage of benign superficial squamous cells displaying radiation effect. Subsequently, the Grahams attributed significance to the presence of small squamous epithelial cells with finely vacuolated cytoplasm, staining lavender in Papanicolaou's stain (**sensitivity response or SR**). They reported that the presence of these cells correlated well with response to radiotherapy. Although the work of the Grahams initially found support, chiefly among Scandinavian workers, it has never received general acceptance.

The concept that there are differences in the individual response to radiotherapy found some initial support in studies by Davis et al (1960). These workers measured the patients' response to radiation by administering **1,500 rads to the mucosa of the cheek of patients with cervical cancer.** By counting **multinucleated squamous cells in smears from the buccal mucosa** as the index of radiation sensitivity, they initially found a surprisingly **good correlation between the response of the buccal epithelium and the radiocurability of cervical cancer.** However, in follow-up studies, the results of treatment were not convincingly favorable in patients with a "good" oral radiation response (Sugimori and Gusberg, 1969).

There is no doubt that the response of the benign squamous epithelium to radiotherapy is quite variable, with some patients showing a remarkable response and others hardly any. Work by Feiner and Garin (1963), from my laboratory, on patients with ovarian and endometrial cancer treated by radiation, disclosed that nearly all the patients had a good radiation response. The reasons for this response remain obscure. In our hands, the correlation of the radiation response to the clinical outcome was not satisfactory.

Cytogenetics and DNA Ploidy as a Prognostic Factor

Atkin and his co-workers (1962, 1964, 1984) and Cox et al (1969) used **cytogenetic techniques** to assess radiosensitivity of invasive carcinoma of the uterine cervix. Atkin's data, based initially on karyotype analysis, and subsequently on DNA measurements, strongly suggested that **patients with aneuploid cervical cancers respond better to radiotherapy and live longer than patients with diploid tumors. Conversely, the prognosis of endometrial and ovarian carcinomas with DNA content in the diploid range was superior to aneuploid cancer.** As discussed in Chapter 11, the issue of DNA measurements in cells derived from precancerous lesions or cancer of the cervix, is highly controversial and may depend a great deal on the techniques used. DNA measurements by image analysis are discussed in Chapter 46 and by flow cytometry in Chapter 47.

EFFECTS OF CANCER CHEMOTHERAPY AGENTS ON EPITHELIA OF THE UTERINE CERVIX

The prototype of chemotherapeutic anti-cancer agents is **mustard gas** [bis(β -chloroethyl)sulfide], a substance first used as a war gas with devastating effects in 1917 during the battle of Ypres. During World War II, it was discovered that a related derivative, the alkylating agent nitrogen mustard (HN_2), was capable of selectively damaging lymphoid tissue in experimental animals. The target of action of alkylating agents is cellular DNA. Cross-linking of the double helix has been documented in vitro (summary in Koss, 1967). This mechanism interferes with the mitotic apparatus of cells and thereby causes cell death and, as a sideline, the morphologic abnormalities. This property of alkylating

P.562

agents has been subsequently utilized in treatment of certain malignant diseases of humans, such as leukemia and malignant lymphomas. Several other alkylating compounds were synthesized during the ensuing years for chemotherapy of cancer.

In the late 1950s, after the introduction of these compounds as therapeutic agents, significant cellular **abnormalities in the squamous epithelium of the uterine cervix were observed in the autopsy material of patients dying of leukemia** (Fig. 18-7). Subsequently, sporadic observations in cervical smears of patients undergoing chemotherapy for various forms of cancer, also disclosed abnormalities of squamous cells (Fig. 18-7B). In retrospect, these changes were **consistent with activation of human papillomavirus (HPV) infection**. In the case illustrated in Figure 18-7A, the patient was a **12-year-old virgin**, strongly suggesting that the viral infection was an activation of a pre-existing virus. Two other alkylating agents, **cyclophosphamide (Cytosan, Endoxan) and busulfan (Myleran) had a major effect on a variety of benign tissues, resulting in significant cytologic abnormalities**.

Cyclophosphamide, an agent extensively used in the treatment of a broad variety of neoplastic diseases, has its effect **primarily on the epithelium of the urinary bladder** and is discussed in Chapter 22.

Busulfan, a drug previously used exclusively in the treatment of **chronic myelogenous leukemia**, was often administered in small doses (1 to 6 mg/day) over several years. Currently, it is also used as one component of chemotherapeutic regimens prior to **bone marrow transplants**.

Its therapeutic effect on neoplastic cells is beyond the scope of this chapter, but Busulfan also causes **notable changes in benign cells of normal organs**. Changes have been observed in the **lungs, the pancreas, the spleen, the urinary tract, the uterine cervix, the breast and other tissues**. Detailed descriptions of the changes in the respiratory and urinary tracts will be found in Chapters 19 and 22, respectively. Changes in the pancreas and the spleen are irrelevant to the topic at hand. A summary may be found in prior publications (Gureli et al, 1963; Nelson and Andrews, 1964; Koss et al, 1965; Feingold and Koss, 1969).

Figure 18-7 Effect of chemotherapy on cervical smears. *A.* Section of the uterine cervix obtained in 1957 at postmortem examination of a 12-year-old girl treated for acute leukemia with a variety of drugs. The tissue pattern closely resembles the warty changes observed in condylomas. Also note scattered nuclear abnormalities. *B.* Effect of Thiothepa administered for a malignant tumor. A large squamous cell resembling a koilocyte is shown in the cervical smear.

Busulfan Effect on Cervicovaginal Smears

The epithelial abnormalities were observed initially in the cervices of five patients receiving busulfan alone and in four patients receiving other forms of therapy in addition to busulfan. Busulfan frequently **induces artificial menopause** after variable periods of administration; the smears assume the **pattern of postmenopausal atrophy**. The abnormalities involving principally squamous cells, resemble those seen in spontaneously occurring low-grade lesions or carcinoma in situ. **Cell enlargement, nuclear enlargement and hyperchromasia, coarse granulation of chromatin, and variation in nuclear size and shape**, may be observed (Fig. 18-8). **Cytoplasmic vacuolization, such as that seen in koilocytes**, was also noted and may represent an infection with (HPV) in immunodeficient patients (see Chap. 11). Because of atrophy, the abnormal cells may show **distortion caused by dryness and, frequently, loss of cytoplasm** (Fig. 18-8C). The changes resemble somewhat late irradiation effect, but the nuclear changes are much more pronounced. In several instances when the patients could be followed, the abnormalities persisted or increased, although the drug was discontinued. The **histologic appearance** of the lesions of the cervix resembles that of spontaneously occurring **low-grade neoplastic lesions** or **flat condyloma** (see Fig. 18-8B,D). There are no studies of HPV in these lesions known to us, but the morphology is strongly **suggestive of a permissive HPV infection**. However, HPV is not likely to be a factor in nuclear abnormalities in the epithelia of lung, breast, or pancreas. The possibility that the alkylating agents are carcinogenic in humans was raised early on by Shimkin (1954) and by Boyland (1964). Interestingly, a patient reported

P.563

by Nelson and Andrews (1964) developed breast cancer while under treatment with busulfan. We have observed two patients, one who developed a carcinoma of the vulva under similar circumstances (Koss et al, 1965) and another who developed invasive carcinoma of the cervix after 5 years of busulfan therapy.

Figure 18-8 Effects of Myeleran (busulfan) effect in cervical smears. *A* Cell changes very similar to spontaneously-occurring koilocytosis were observed several years after onset of busulfan treatment for chronic myelogenous leukemia. *B*. Biopsy of cervix corresponding to *A* showing a “wart-like lesion” with marked koilocytosis, suggestive of an active HPV infection. *C*. Nuclear enlargement and hyperchromasia in an atrophic smear of a woman treated with busulfan for chronic myelogenous leukemia. *D*. Postmortem changes in the squamous epithelium of the uterine cervix of the patient shown in *C*. The change is suggestive of human papillomavirus activation.

Other alkylating agents, such as **Thiotepa**, may occasionally induce similar abnormalities of squamous cells in cervical epithelium (see Fig. 18-7B). It is known that patients surviving an intensive course of chemotherapy for various cancers are at a high risk for future cancers and their benefit must be carefully assessed in view of the risk factors (Kyle et al, 1975; Leone et al, 1999; Oddou et al, 1998).

IMMUNE DEFICIENCY

Immunosuppressive Agents in Organ Transplantation

Suppression of the human immune system has been introduced into the medical armamentarium with the onset of the era of **organ transplantation**. To prevent rejection of the transplanted organ, it became important to suppress, at least temporarily, the natural immune rejection mechanism. Immunosuppression may also be incidental to cancer chemotherapy (see above). Several of the alkylating and other chemotherapeutic agents are immunosuppressive by depressing one or more of the cell types active in immune response (see Chap. 5). Some of the most important immunosuppressive agents currently used are **cyclosporine**, **azathioprine (Imuran)**, **human anti-lymphocytic serum**, **certain corticoids such as prednisolone**, and **certain alkylating agents such as cyclophosphamide (Cytosan, Endoxan) and busulfan (Myeleran)**. The mechanisms of action of these various agents are very different and the interested reader is referred to other sources for further information.

The introduction of immunosuppression on a large scale, while effective in preventing transplant rejection in many patients, has substantially increased the frequency of certain

disorders that hitherto were extremely rare. This pertains to several bacterial, fungal, and viral diseases, which are discussed in Chapters 10 and 19 and to recognition that for the **immunosuppressed patient, there is a significantly increased risk of cancer** (Kyle et al, 1975; Oddou et al, 1998; Leone et al, 1999). The same applies to **patients with the acquired immunodeficiency syndrome (AIDS)**. Although the most frequently observed malignant tumors

P.564

are malignant lymphomas, a very wide spectrum of other types of malignant tumors have been observed.

The uterine cervix is among the high-risk organs. Gupta et al (1969) were the first to record a case of **cervical dysplasia associated with azathioprine therapy**, followed by a report by Kay et al (1970). Besides various levels of intraepithelial neoplasia (dysplasia, carcinoma in situ), invasive carcinomas have also been observed (for summary, see Chassot et al, 1974; and Penn, 1969, 1980, 1981).

The **cervical cytologic abnormalities** in the immunosuppressed patient are generally **similar to those observed in routine material from patients with precancerous lesions or cancer of the cervix** (Fig. 18-9A,B). Occasionally, however, **unusually large sizes and bizarre configuration of the abnormal cells may be observed** (Fig. 18-9C,D). These epithelial abnormalities are capricious and their significance is unpredictable: in some instances, a carcinoma in situ has been observed and treated (see Fig. 18-9A,B); in other instances, the cell changes disappeared after arrest of immunosuppressive therapy (see Fig. 18-9C,D). The experience to date strongly suggests that long-term follow-up of these patients, many of whom are very young, should be the rule, as is true with similar patients of the nonimmunosuppressed group. Again, the possibility that human papillomavirus may play a role in these changes cannot be ruled out.

Figure 18-9 Effects of immunosuppressive drugs. *A.* Markedly atypical cervical smear in a 27-year-old woman who received a renal transplant 2 years prior. *B.* A classical carcinoma in situ (HGSIL) observed in the patient shown in *A.* *C,D.* Atypia of squamous cells observed in a 24-year-old renal transplant recipient. The change vanished after

reduction in the dosage of immunosuppression drugs. (*C,D* case courtesy of Dr. Clifford Urban.)

Other Forms of Immunosuppression

In a study of cervical and vaginal lesions associated with human papillomavirus (HPV), Shokri-Tabibzadeh et al (1981) reported from this laboratory on four women, three with **treated Hodgkin's disease** and one with a **not-further-classified form of immune deficiency**. In the four women, **cytologic and histologic neoplastic changes** were observed, and the presence of **viral particles** could be documented by electron microscopy (see Fig. 11-6). In one of these women, an invasive carcinoma of the vulvar introitus was observed. The **immune deficiency** of patients with treated **Hodgkin's disease** is well known and such patients are at a very high **risk for development of other tumors** (Arseneau et al, 1977; Brody et al, 1977; Krikorian et al, 1979; Tucker et al, 1988). The **uterine cervix** appears to be a major target, probably because of **superinfection with HPV and its consequences**.

The confirmation of this relationship was obtained from a study of women with **AIDS**. As summarized in Chapter 11, women with AIDS have a statistically significant greater increase in HPV-associated cytologic abnormalities than that found for AIDS-free controls, matched for age, race, and sexual activity. Numerous other observations on the relationship have documented that AIDS is a major risk factor for cervical cancer precursors and invasive cancer.

P.565

ORAL CONTRACEPTIVE DRUGS

Oral Contraceptives and Cervical Intraepithelial Neoplasia

Widespread use of contraceptive hormonal agents has stimulated interest in the possible impact of these drugs on carcinogenesis of the uterine cervix. The studies were triggered by fortuitous observations that recipients of Planned Parenthood advice apparently had a high rate of precancerous lesions of the uterine cervix. Several such studies are now on record and they generally show a **trend toward higher rates of cervical epithelial neoplasia among women users of oral contraceptive drugs** than in the control groups who use barrier contraceptives (Melamed et al, 1969; see also Chap. 11). However, there is no agreement on whether the differences are attributable to the effect of the drugs, to a protective effect of barrier contraception, or to the social and behavioral characteristics of the women selecting oral contraceptives in preference to other modes of birth control. It is possible that **protection from human papillomavirus superinfection** is provided to women using barrier contraceptives. Regardless of these considerations, Planned Parenthood clinics now generally offer cytologic screening to women requesting and using contraceptives, undoubtedly with beneficial results for the recipients.

Figure 18-10 Effect of contraceptive medication. *A.* Enlarged nuclei of endocervical cells in a 27-year-old woman, a long-term user of contraceptive medication. *B.* The same patient 6 months after discontinuation of therapy. The endocervical cell pattern was completely normal. *C.* A multinucleated endocervical giant cell, strongly resembling the Arias-Stella phenomenon in a patient on contraceptive medication. *D.* Biopsy of endocervix corresponding to smear shown in *C.* The endocervical lining shows several large cells with hyperchromatic nuclei. The abnormality disappeared 6 months after discontinuation of medication.

There are no known morphologic differences in the cytologic presentation of precancerous lesions and carcinoma of the uterine cervix in the users of any of the current methods of contraception.

Other Effects

Oral contraceptives that contain progesterone may cause nuclear enlargement in isolated endocervical cells, which can be quite substantial (Fig. 18-10A,C). The changes, when seen in histologic material, often are **combined with microglandular hyperplasia** (see Chap. 10), wherein **single endocervical cells have enlarged, hyperchromatic nuclei, akin to the Arias-Stella phenomenon in pregnancy** (Fig. 18-10D; also see Chap. 8). After discontinuation of

P.566

the drugs, the changes usually disappear (Fig. 18-10B). Although the exact mechanism of this phenomenon is not known, it may be assumed that the large cells have polyploid nuclei, as has been shown for the Arias-Stella phenomenon. The differential diagnosis comprises dyskaryotic or malignant endocervical cells. The drug-induced changes are usually limited to a few endocervical cells, surrounded by a population of normal nuclei. In case of doubt, discontinuation of the drug and follow-up studies will usually solve the dilemma.

Liver Abnormalities in Users of Oral Contraceptives

Although this subject is of no consequence for gynecologic cytology, it must be mentioned that abnormalities of the liver in the form of **hamartomas, adenomas, and even hepatomas and angiosarcomas**, have been observed in women using oral hormonal contraceptives. The pertinent references are listed in the bibliography. For cytologic manifestations of liver lesions in aspirated samples, see Chapter 38.

The Lower Respiratory Tract in the Absence of Cancer: Conventional and Aspiration Cytology

Myron R. Melamed

P.569

ANATOMY

The respiratory tract serves the dual purpose of supplying oxygen to and removing carbon dioxide from the circulating blood. This exchange takes place at the level of the pulmonary alveoli. Oxygen-rich air is inhaled, and carbon-dioxide rich air is exhaled through a complex series of conduits extending from the upper or cranial portions of the respiratory tract (e.g, the nasal cavity and the mouth^{*}) to the thinwalled terminal alveoli of the lung via the larynx, trachea, and bronchi. The trachea and main bronchi are rigid, resisting collapse as pressures within the thorax change during respiratory movements. The musculature of the thorax and the diaphragm initiate inspiration by expanding the thoracic cage, thereby creating negative pressure within the pleural cavity that is transmitted to the elastic lungs. A very thin layer of fluid facilitates the movement of the pleural surfaces against each other (see anatomy of the serous cavities in Chap. 25).

The respiratory tract may be roughly divided into three portions. The cranial portion is supported by the bones of the skull and the cervical vertebrae; it comprises the nasal cavity and the paranasal sinuses, the buccal cavity, and the pharynx. The intermediate portion is composed of the larynx, trachea and the main bronchi; it stretches from the larynx to the hilus of each lung. The third portion is the lung proper, composed of lobar, segmental and smaller bronchi, and the alveolar system with its extraordinarily rich blood supply (Fig. 19-1A). A brief discussion of the various anatomic components follows.

Upper Airway

The **nasal cavity** functions principally as a conduit for inspired air, but also serves in warming and moistening the air, and trapping larger dust particles. It is subdivided by the turbinate bones into **three compartments**, of which the uppermost is partially lined by the **olfactory mucosa** containing receptors for the sense of smell. The middle and lower compartments are purely respiratory. All three nasal compartments communicate through small orifices directly into the **paranasal sinuses**. The nasal cavity opens posteriorly into the **pharynx**, a space demarcated posteriorly by the spine and its muscles, reaching upward to the base of the skull and downward to be in direct continuity with the esophagus and the larynx. Of importance within the pharynx is the presence of rich deposits of **lymphoid tissue**, especially the tonsils, located anterolaterally on each side of the pharynx, and the pharyngeal or third tonsil (adenoids) located posteriorly near the base of the skull. The **mouth** or **buccal cavity** also opens posteriorly into the pharynx; the **tongue** with its complex and exquisitely developed musculature occupies the central portion of the buccal cavity. The ducts of numerous **salivary glands** open into the buccal cavity, providing a constant flow of saliva.

Intermediate Airway

Inferiorly, the pharynx communicates with the **larynx** anteriorly and continues posteriorly as the **esophagus**. The **epiglottis** forms a lid capable of closing the larynx during the act of swallowing and thereby prevents entrance of food particles into the lower respiratory tract. The larynx is contained within a system of cartilages and is in direct continuity with the **trachea**, a semi-rigid tube kept open by C-shaped rings of cartilage that are incomplete posteriorly where the trachea is in contact with the esophagus. Within the thorax, approximately at the level of the fourth thoracic vertebra, the trachea divides into two main branches—the **left and right mainstem bronchi**.

Lower Airway

Each mainstem bronchus enters the corresponding lung accompanied by branches of the pulmonary artery and veins

P.570

in an area designated as the **hilus**. The **left lung** is partially separated by fissures into **two lobes**; the **right lung** has **three lobes**. Thus, the mainstem bronchi divide into **two lobar bronchi on the left and three on the right**. Subsequently, each lobar bronchus divides into **segmental bronchi** (10 on the right and 9 on the left; Fig. 19-1B), which undergo 18 dichotomous divisions into **subsegmental bronchi and bronchioles** that, in turn, form the thin-walled **respiratory bronchioles**, each of which opens into several alveoli. Although the lumina of individual bronchi become smaller with each bronchial division, the total air-carrying volume increases progressively to reach its greatest capacity at the level of the alveoli, which form the bulk of the pulmonary parenchyma.

Each **alveolus** is a small, thin-walled sac, described in detail below. Capillary branches of the **pulmonary artery** run in the alveolar walls or **alveolar septa**, bringing blood that is poor in oxygen from the right ventricle and carrying away oxygenated blood in interlobular venules to pulmonary veins to the left atrium. The exchange of gases takes place across the alveolar wall. The lung itself is nourished by branches of the **bronchial arteries** that come from the aorta and follow the branching bronchi into the lung along with the pulmonary vessels, returning blood through the pulmonary veins.

Except at the hilus, the lungs are entirely surrounded by the **visceral layer of the pleura**.

HISTOLOGY OF THE NORMAL RESPIRATORY TRACT

Epithelial Lining

Two principal types of epithelium are encountered within the upper respiratory tract and the bronchial tree: **nonkeratinizing, stratified squamous epithelium**, which has no distinguishing features, and a characteristic **respiratory epithelium**. The **olfactory mucosa**, present in the uppermost portion of the nasal cavity, does not play a significant role in the cytology of the respiratory tract. The epithelia lining the respiratory alveoli and the alveolar macrophages will be described separately.

Squamous Epithelium

Stratified squamous epithelium lines the anterior portion of the **nasal cavity**, the **mouth**, **tonsils**, and central and lower portions of the **pharynx**. In general, the mucosa overlying and tightly adherent to bony structures, the hard palate, for example, and buccal mucosa that is subject to chronic irritation as in patients with poor dental hygiene, tends to form a superficial layer of keratin and therefore appears white; elsewhere throughout most of the mouth and oropharynx, it is nonkeratinizing (Fig. 19-2A). In the **larynx**, the upper or buccal aspect of the **epiglottis** is lined by nonkeratinizing stratified squamous epithelium, and the **vocal cords** are lined by a layer of thin, yet mechanically very resistant squamous epithelium (Fig. 19-2B). The remainder of the laryngeal mucosa may show islands of stratified squamous epithelium alternating with respiratory epithelium.

Respiratory Epithelium

Respiratory epithelium surfaces the major portion of the **nasal cavity**, the **paranasal sinuses**, the upper or nasal portion of the **pharynx and adenoids**, parts of the **larynx**, all of the **trachea**, and the **bronchial tree** (McDowell et al, 1978).

The respiratory epithelium is a **pseudostratified columnar epithelium**, characterized by the presence of **ciliated columnar cells** with interspersed **mucus-secreting goblet cells**. The term *pseudostratified* is used to describe epithelia

P.571

with nuclei located at different levels, hence the stratified appearance, although most cells are attached to the basement membrane. **The cilia** are anchored to the luminal surface of the bronchial cells by a row of points of attachment, combining to form a readily visible dark line or **terminal plate** (see Chap. 2). At their opposite end, where the columnar cells attach to the basement membrane, they are tapered, leaving a triangular space between the cells within which are small, triangular **basal or reserve cells** that are the source of epithelial regeneration. The basic structure of the respiratory epithelium is illustrated in Figure 19-3A.

Figure 19-2 Stratified squamous epithelium. A Oral mucosa. Note the similarity to squamous epithelium of the vagina, which is characteristically layered and matures toward

the surface. There is no keratinization. **B. Vocal cord.** The epithelium is stratified squamous but composed of tightly coherent small cells.

The **goblet cells** derive their name from an approximately triangular shape, resembling a wine goblet, with the nucleus placed at the narrow, basal end of the cell, while the clear supranuclear cytoplasm is distended by mucus-forming small vacuoles (Fig. 19-3B). The number of goblet cells is variable. They may be numerous under certain pathologic circumstances, such as chronic bronchitis and asthma. The fine structure of ciliated columnar and goblet cells is shown in an electron micrograph in Figure 19-3C. The goblet cells **produce a thin layer of mucus** that carpets the surface of the ciliated epithelium. This **mucus carpet** (also known as the **mucociliary escalator**) captures respired dust particles and is kept moving by the coordinated motion of the beating cilia in the direction of the larynx where it is removed by coughing. This function is lost in patients who suffer from genetic abnormalities of ciliary structure and function known as **immobile ciliary syndrome**, discussed below.

Within the trachea and the main bronchi, the epithelium is truly stratified with two, three, or more layers of columnar cells, not all of which reach the surface. The cells that do not reach the surface have no cilia, an example of cellular differentiation determined by spatial arrangement. Goblet cells and ciliated cells progressively decrease in number in the smaller bronchial branches, and give way to nonciliated columnar and cuboidal cells. The epithelium of the smaller bronchioles is single layered and epithelial cells are low, columnar, or cuboidal.

The terminal bronchiolar epithelium includes **Clara cells**, nonmucus-secreting cells that produce **surfactant** (see below). They are characterized by protruding apical cytoplasm containing PAS-positive, diastase-resistant secretory material (Fig. 19-3D) and characteristic electron-dense, apical cytoplasmic granules (Cutz and Conen, 1971). They can be identified also by immunocytochemical staining with antibody to human surfactant-associated glycoproteins (Balis et al, 1985).

A small number of basally placed **neuroepithelial cells** known as **Feyrter** or **Kulchitsky** cells also are present, primarily at airway bifurcations. They are most numerous in fetal lungs but relatively sparse in the adult and are characterized by dense core neurosecretory granules in electron micrographs. In some individuals living at high altitudes or with chronic lung disease, there may be multiple minute **hyperplastic nests of these neuroendocrine cells**, which have been termed **tumorlets**. They have been shown to secrete a number of polypeptide hormones (McDowell et al, 1976b), including corticotropin that in one reported case was the cause of **Cushing's syndrome** (Arioglu et al, 1998). The Kulchitsky cells are considered to be the parent cells of carcinoid tumors (see Chap. 20).

The terminal bronchioles open into a vestibule-like respiratory bronchiole with nearly flat epithelium from which respired air enters several communicating alveoli.

The Alveoli

The roughly spherical thin-walled alveolus is the functional unit of the lung, where exchange of oxygen and carbon dioxide takes place between air space and capillary. Ultrastructural studies have shown the wall of the alveolus to be surfaced by two types of epithelial cells, pneumocytes type I and pneumocytes type II, represented schematically in Figure 19-4A.

Pneumocytes type I are flattened cells, few in number, with extremely attenuated cytoplasm that surfaces at least 90% of the alveolar wall. They have few cytoplasmic organelles, are metabolically inactive, cannot be visualized in conventional histologic sections, and are not capable of regeneration.

Figure 19-3 Respiratory epithelium of a medium-sized bronchus and terminal bronchiole. *A.* The characteristic pseudostratified appearance of this ciliated columnar epithelium is due to the midcellular location of nuclei of the columnar cells and the basal location of nuclei of the small basal or reserve cells that lie between tapered ends of the columnar cells at their attachment to the basement membrane. *B.* Mucus-secreting goblet cells are interspersed between the ciliated columnar cells in this section of bronchial mucosa. The goblet cells are increased in patients with asthma or chronic bronchitis. *C.* Electron micrograph showing the ciliated columnar epithelial cells and interspersed goblet cells. Mucus is being extruded from the goblet cells. *D.* The respiratory epithelium of the terminal bronchiole is single-layered, cuboidal and nonciliated. Interspersed surfactant-secreting Clara cells are PAS positive (stained red). (*C*: Courtesy of Dr. R. Erlandson, $\times 1,600$.)

The remaining 10% of the alveolar surface is occupied by more plump, rounded, or cuboidal **pneumocytes type II**. Although they too are scarcely (if at all) visible in conventional histologic sections of normal lung, these cells are capable of proliferating and can become hyperplastic in a broad variety of chronic inflammatory lung diseases. They are the source of regenerating pneumocytes type I. They express epithelial cytokeratins (Fig. 19-4B), are metabolically very active and, like the Clara cells, they synthesize **alveolar surfactant, a detergent-like protein that lines the inner surface of the alveoli, lowering surface tension and preventing collapse of the air spaces** (Fig. 19-4C) (Groniowski and Byczyskova, 1964; Askin and Kuhn, 1971). Surfactant accumulates in the cytoplasm of pneumocytes type II in the form of characteristic, large **osmiophilic lamellar inclusions** that can be demonstrated by electron microscopy (Fig. 19-4D). **The precursor proteins of surfactant and the lamellar inclusions are markers of pneumocytes type II**. As noted, these cells can regenerate if injured, and are also capable of differentiating into pneumocytes type I (Kasper and Haroske, 1996).

Pneumocytes are not likely to be recognized in specimens of sputum or bronchial brushing, but they can be identified in bronchoalveolar lavage (BAL) and fine-needle aspiration (FNA) specimens of lung from patients with chronic lung disease and may be mistaken for adenocarcinoma (see below).

Pulmonary Alveolar Macrophages

In histologic material that has been handled carefully and processed without excessive delay, large phagocytic cells containing particles of dust are observed within nearly all of the alveoli (Fig. 19-5). These cells are sometimes referred to as **dust cells** or **pneumocytes type III**. Exceedingly large numbers of macrophages may be observed in the alveoli of

P.573

people who are heavy cigarette smokers or live in a dusty atmosphere. The ultrastructure of alveolar macrophages is consistent with a metabolically active cell provided with microvilli, lysosomes, and vacuolated inclusions. The **bone marrow origin** of alveolar macrophages was demonstrated in mice by Brunstetter et al (1971), and in humans by Thomas et al (1976) and Nakata et al (1999) who used the **FISH** (fluorescent in situ hybridization) technique (see Chaps. 3 and 4) to demonstrate a Y chromosome in the alveolar macrophages of a female recipient of bone marrow from a male donor. The **phagocytic function of alveolar macrophages** is called upon in terminal bronchioles and alveoli where the respiratory tract lacks cilia, thus providing an additional defense against inspired foreign particles. In a series of ingenious experiments, Harmsen et al (1985) have shown that labeled particles instilled into the lung are not passively transported across the alveolar membrane but are phagocytized by alveolar macrophages that then migrate to lymph nodes.

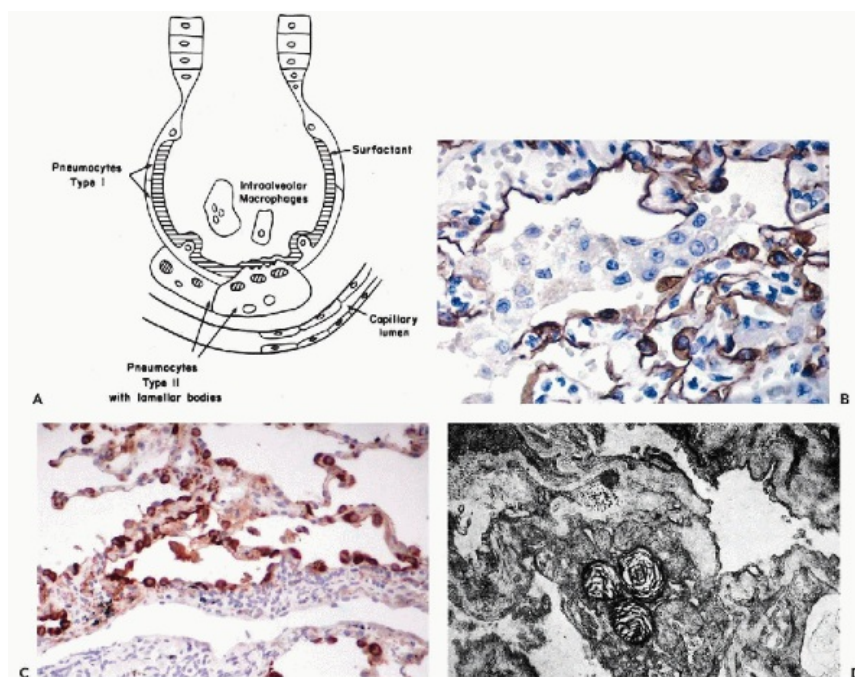

Figure 19-4 Pulmonary alveoli. A. Schematic representation of the ultrastructure of the alveolus showing pneumocytes type I and II, the latter with large nuclei and abundant cytoplasm within which are osmiophilic, dark inclusions. Overlying the pneumocytes is a layer of surfactant, and in the alveolar wall is a capillary separated from the alveolus by a basement membrane. B. The alveolus here is stained with anti-cytokeratin antibody (AE1/AE3) that demonstrates plump pneumocytes type II surfacing the alveolar wall, and the flat, greatly attenuated cytoplasm of type I pneumocytes. Pulmonary macrophages lie within the lumen of the alveolus. (Immunoperoxidase reaction with hematoxylin counterstain.) C. Immunoperoxidase reaction with anti-surfactant antibody, identifying the surfactant produced by pneumocytes type II. D. Electron micrograph of an alveolus showing the concentrically laminated cytoplasmic inclusions of surfactant precursor in the cytoplasm of a type II pneumocyte. (C: Courtesy of Dr. Allen Gown.) (D: $\times 1,600$).

CYTOLOGIC SAMPLING METHODS

Sputum

Spontaneously produced or artificially induced sputum is by far the simplest and most useful method of investigating

P.574

the respiratory tract. Multiple samples can be obtained at home or in the doctor's office or clinic without discomfort to the patient, and the diagnostic yield is excellent in many benign and nearly all malignant disorders. Patients should be instructed that the diagnostic material comes from deep portions of the lungs. They should be told to clear their nasal passages and rinse their mouth with water, discarding that material before collecting a specimen. **Ideal diagnostic material is obtained from a spontaneous deep cough**, which should be expelled directly into a wide-mouth container with fixative (vodka or whiskey will do, if necessary) and stored in the refrigerator where it can remain for as long as 2 to 3 weeks before processing in the laboratory. Often the best specimens are obtained on arising in the morning when a change in position will initiate a deep cough that expels bronchial secretions accumulated overnight.

Figure 19-5 Alveolar macrophages within the alveoli.

Unfortunately, few patients are adequately instructed in how to produce a good deep cough specimen, and the material submitted may consist entirely of mouth contents or **saliva that is of no diagnostic value**. Even with good cough specimens, the presence of contaminating material from the mouth or nasopharynx can obscure diagnostic cells and make evaluation more difficult.

For patients with a nonproductive cough or no cough, it is possible to induce coughing by inhalation of a heated aerosol of 20% polypropylene glycol in hypertonic (10%) saline (or in water if the patient is salt restricted). One container may be used to collect three or four deep cough specimens. The composition of an adequate sputum sample is described below, and methods of processing are described in Chapter 44.

Bronchial Brushings

With the introduction of flexible bronchoscopes (Fig. 19-6) capable of reaching subsegmental bronchi, the cytologic diagnosis of lung cancer relies heavily on direct bronchial brushings. Cell samples are obtained with a small brush threaded through a separate channel in the fiberoptic bronchoscope, guided to a selected site under visual control. The method permits sampling of a visualized mucosal abnormality or systematic sampling of all segmental bronchi to **confirm and localize occult in situ or early invasive carcinomas** detected by sputum cytology or suspected radiologically. Brushings may be supplemented by tissue biopsies or by transbronchial aspiration biopsy of lesions within reach of the fiberoptic bronchoscope, but in our experience, are less useful than BAL specimens for diagnosis of a more distal peripheral bronchoalveolar carcinoma.

Figure 19-6 Flexible fiber bronchoscope and a rigid bronchoscope.

Bronchial Aspirates and Washings

Although **brushings provide a better sample of the bronchial mucosa at a given site or sites, aspirates and washings provide information on the status of the respiratory tract in small bronchi beyond reach of the bronchoscopic brush.** Bronchial washing specimens are obtained under bronchoscopic guidance by first aspirating the accumulated contents of the bronchus (or bronchi) in an initial sample. Then, additional samples are obtained by repeatedly instilling and reaspirating (about 50 ml) normal saline from the selected bronchus or bronchi. The composition of samples is discussed below, and methods of processing it can be found in Chapter 44.

Bronchoalveolar Lavage (BAL)

BAL was introduced initially as a **therapeutic** procedure to clear the alveolar spaces of accumulated secretions blocking gaseous exchange, for example, in **alveolar proteinosis** (see below) and **bronchial asthma** (summary in Ramirez et al, 1965). Subsequently, the technique has been used for **diagnostic** purposes primarily in suspected ***Pneumocystis carinii* pneumonia**, replacing open lung biopsy (Stover et al, 1984; Fleury et al, 1985), and in the diagnosis of interstitial lung disease (Stoller et al, 1987). It has been used to identify various other **bacterial, fungal, parasitic, and sometimes viral** agents causing pulmonary infections,

particularly in patients with **acquired immunodeficiency syndrome (AIDS)** (Broaddus et al, 1985; Kraft et al, 1998; Scaglia et al, 1998) and children with chronic granulomatous disease,

P.575

an inherited defect of phagocytic oxidative enzymes (Abati et al, 1996). It has also been reported of value in investigating and monitoring other inflammatory reactions in the lung, for example **ozone injury** of the alveolar epithelium (Bhalla, 1999), **bronchiolitis obliterans organizing pneumonia (BOOP)** (Lamont et al, 1998) and chronic pulmonary diseases, mainly **sarcoidosis** and various forms of **pulmonary pneumoconioses**. In patients suspected radiologically of having pulmonary **alveolar microlithiasis**, a rare disease characterized by the presence of alveolar calcospherites, the calcospherites can be demonstrated in BAL fluid (see below) (Mariotta et al, 1997).

A recent and important application of BAL is in detecting rejection and/or infection in recipients of **lung transplants**. Rejection is heralded by an increasing percentage of polymorphonuclear leukocytes in the lavage specimen (Chan et al, 1996; Henke et al, 1999). BAL may sometimes disclose an unsuspected carcinoma, particularly **bronchoalveolar carcinoma**, which can mimic diffuse inflammatory lung disease radiologically and has been reported in patients monitored after lung transplantation (Garver et al, 1999).

Procedure

Under local anesthetic, the bronchoscope is passed to the lung segment of interest, usually a secondary or tertiary bronchus, and wedged to occlude the bronchial lumen. From 100 to 300 ml of normal saline is instilled in 20 to 50 ml aliquots, reaspirated, and the collected fluid is forwarded to the laboratory for processing. Evaluation of the lavage fluid is based on differential cell counts and immunophenotyping the cells present, as well as chemical analysis and bacteriologic study of the fluid retrieved from the alveolar spaces (Reynolds and Newball, 1974; summaries in Reynolds et al, 1977; Hunninghake et al, 1979; Crystal et al, 1984; Bitterman et al, 1986). If the lavage is properly performed, the cell content will be limited to the epithelium of the bronchioles beyond the point of occlusion and to the contents of the alveoli, mainly alveolar macrophages and inflammatory cells. Certain characteristics of the macrophages may be evaluated, for example, their ability to produce fibronectin or other factors stimulating the growth of fibroblasts leading to pulmonary fibrosis (Bitterman et al, 1983). The proportion and type of immunostimulated lymphocytes and the presence or absence of polymorphonuclear leukocytes also may be useful in evaluating the nature of the pulmonary disorder. The fluid may also be examined for the presence of surfactant. Recognition of microorganisms is described below.

Needle Aspiration Biopsy

The general principles of aspiration biopsy technique are discussed in Chapter 28. Special features of needle aspiration biopsy of the lung are described here and in Chapter 20.

There are two techniques of pulmonary aspiration biopsy: **percutaneous aspiration** of lung lesions and **transbronchial aspiration** via fiberoptic bronchoscopy. Percutaneous needle biopsy of the lung is most commonly performed to investigate peripheral lesions that are inaccessible to the bronchoscope and do not desquamate cells into the bronchial tree. Computed tomography (CT) or, less commonly, ultrasound is used to guide the direction and depth of insertion of the biopsy needle; fluoroscopy is no longer used. Transbronchial needle aspirates, first suggested by Wang et al (1981), serve to sample enlarged para-hilar or para-bronchial lymph nodes or other near-hilar masses that cannot easily be reached by percutaneous needle biopsy.

Contraindications to percutaneous needle biopsy include the following:

- Hemorrhagic diathesis
- Anticoagulant therapy (unless previously discontinued with restoration of normal clotting time)
- Severe pulmonary hypertension
- Advanced emphysema
- Suspected arteriovenous malformation or aneurysm
- Suspicion of hydatid cyst (see below)
- Uncooperative patient

Percutaneous Biopsy With Small-Caliber Needles (FNA)

When the lesion is close to the chest wall, it can be reached with a thin, relatively short needle (external diameter, 0.6 mm; length, 10 cm). For deeper lesions, a longer, flexible needle (14 to 20 cm) with the same diameter can be inserted through a thicker (17-gauge) needle that serves as a guide.

Local anesthesia is applied to the chest wall and pleura. The guide is introduced into the chest wall, care being taken not to let it penetrate into the pleural space. The finer needle is inserted through the guide, and when it reaches the target in the lung, the aspiration is performed, moving the needle to and fro as for palpable lesions. A **single-grip syringe** may be used to assist in the aspiration procedure (see Chap. 28).

Percutaneous Aspiration With Large-Caliber Needles

Thin needles may be unsuitable for small (2 cm or less) deep-lying lesions. Such needles may bend during passage through the pulmonary parenchyma, and the target may be missed. A wider bore, sturdy needle (0.9 to 1 mm external diameter) will not bend easily and may be more accurately guided to the lesion. A stylus inserted into the needle lends additional rigidity to the needle and also prevents tissues from the thoracic wall entering the lumen of the needle as it is inserted.

The technique of aspiration biopsy with a large-caliber needle is as follows. The patient is usually positioned horizontally on an adjustable table. An entry point, marked on the skin, is chosen so that the lesion can easily be reached. The skin, chest wall, and pleura are anesthetized. Premedication and general anesthesia are usually not necessary. With CT guidance, the needle is inserted at the designated entry point (close to the upper margin of a rib to avoid the intercostal artery) and introduced into the lesion. Care is taken to avoid large blood vessels and bronchi. The patient is instructed to breathe normally. When the needle has

P.576

reached the lesion, a change in consistency usually will be noticed. With the tip of the needle in the lesion, the operator rotates it clockwise and counter-clockwise to loosen small tissue fragments around the tip. The stylus is then withdrawn, a 10- or 20-ml syringe is attached, and **the loosened tissue is aspirated into the needle while the patient holds his or her breath**. The aspirated material need not (should not) be drawn beyond the lumen of the needle. Negative pressure is released and the needle is withdrawn from the chest. The aspirated material is expressed onto glass slides; the number of slides depends on the amount of aspirate. Air-dried and wet-fixed smears are prepared. The needle may be washed with sterile normal saline and the contents are preserved for cell blocks or for bacteriologic examination.

Screw-Needle Biopsy

Now rarely used, this method is of historical interest as a technique designed to obtain diagnostic material from **fibrocalcific granulomas, hamartomas, and other lesions that are not easily penetrated or aspirated with a regular needle**. The intent is to avoid exploratory thoracotomy for diagnosis of a benign lesion. The procedure of inserting the needle is the same as for the large-caliber needle, described above. When the large-caliber needle reaches the lesion, **the stylus is removed and replaced by one with a sharp point on a screw tip that is rotated into the target mass**. The tumor, now fixed by the screw, can be penetrated by the needle. After some rotary movements, the instrument is withdrawn from the chest. The screw stylus is removed from the needle, and loose cellular material is deposited on a glass slide by rotating the screw. The material is smeared on one or more slides, except for sizeable tissue fragments that are embedded in paraffin for sectioning (Dahlgren and Nordenström, 1966).

Complications of Percutaneous Aspiration Biopsy

Serious complications are rare. The three most common complications of immediate importance are **pneumothorax, hemorrhage, and air embolism**. Also important, but exceedingly rare and of less immediate concern, is the possibility of seeding cancer in the needle track.

Pneumothorax

The frequency of pneumothorax among patients in the Karolinska Hospital series, who underwent single or multiple aspiration biopsies to obtain a cytologic diagnosis, was about 27% (Dahlgren and Nordenström, 1966). An approximately similar frequency of pneumothorax was recorded at Montefiore Medical Center. In most cases, the pneumothorax is asymptomatic and detected only by follow-up chest x-ray taken routinely after 6 to 12 hours; it resolves spontaneously, and no treatment is necessary. In about 3% of patients, the pneumothorax requires hospitalization and treatment (Kamholz et al, 1982). Factors influencing the frequency and severity of pneumothorax include the size and site of the lesion, the patient's age, presence of emphysematous blebs, and the operator's experience. Pneumothorax is more common in elderly patients and in patients with small, deeply seated lesions. The risk of pneumothorax precludes aspiration biopsy of the lung as an office procedure. It should be performed only where emergency thoracic surgical assistance is available if needed.

Hemorrhage

Some bleeding into the lung can be expected with every needle aspiration biopsy. In most cases, the bleeding is of no consequence. An occasional patient will experience transient hemoptysis, but we have not encountered more severe or persistent hemoptysis. In one instance, cardiac tamponade was reported following FNA of a lesion near the mediastinum (Kucharczyk et al, 1982).

Air Embolism

Aberle et al (1987) reported the death of a patient with Wegener's granulomatosis due to air embolism following percutaneous FNA. This extremely rare complication was never encountered during a series of 3,799 aspiration biopsies of the lung on 2,726 patients from Karolinska Sjukhuset (Dahlgren and Nordenström, 1966), nor has it been observed in many hundreds of patients at Montefiore Medical Center and Westchester Medical Center.

Spread of Cancer in the Needle Track

This complication is extremely rare. In the Karolinska Hospital series, more than 1,250 pulmonary carcinomas were diagnosed by aspiration biopsy, but implantation metastasis was reported in only one patient, a 73-year-old man with inoperable squamous cell carcinoma (Sinner and Zajicek, 1976). Sacchini et al (1989) reported implants of pulmonary

adenocarcinoma in the chest wall of a 57-year-old woman 3 months following percutaneous FNA and resection of the lung cancer; a single additional case was reported by Moloo et al (1985). Similar complications were observed and illustrated by Koss et al (1992) and by Yoshikawa et al (2000). Considering that many thousands of such procedures are performed annually worldwide, this complication is still rare enough to be reportable.

Transbronchial Needle Aspiration

Transbronchial needle aspiration, first described in 1981 by Wang et al, is performed **during bronchoscopy** when an extrabronchial lesion is suspected. A thin, flexible needle is inserted through the bronchial wall into the suspected lesion via the bronchoscope, and the cellular material is aspirated and processed as for percutaneous biopsies.

CYTOLOGY OF THE NORMAL RESPIRATORY TRACT

Squamous Epithelium

The squamous epithelium of the buccal cavity is constantly washed by saliva; therefore, the changes induced by cellular dryness are exceedingly uncommon. The exfoliated **superficial squamous cells**, which predominate in specimens of saliva as they do in scrape smears of other squamous mucosal surfaces, are similar in all respects to the superficial and intermediate squamous cells of the female genital tract.

P.577

There may be karyomegaly of occasional cells without apparent significance (Fig. 19-7A). Occasionally also, smaller **squamous cells** with relatively large but uniform nuclei may be present, comparable to the parabasal cells of cervicovaginal cytology specimens (Fig. 19-7B). They may be present singly, but are often in plaques and encountered more commonly in **inflammatory disorders** of the oral cavity. They are presumed to represent incomplete maturation of regenerating epithelium. **Onion-like arrangements of benign squamous cells (i.e., squamous pearls)** (Fig. 19-7C) and occasionally small spindly squamous cells also may be observed. **Anucleated squamous cells** are few, if present at all, but may exfoliate from the normal mucosa overlying and fixed to bone (e.g., hard palate), or from sites of chronic irritation as occurs with poor dentition. The presence of large numbers or plaques of anucleated squames (Fig. 19-7D) is abnormal and is an indication of **oral leukoplakia** (see Chap. 21).

Respiratory Epithelium

Contrary to squamous epithelium, which desquamates easily and is well represented in all exfoliated samples, the **normal respiratory epithelium does not desquamate freely**. Consequently, cells derived from this epithelium are **uncommon in sputum** and are typically seen in **specimens obtained by bronchial brushing or aspiration**, or after other procedures that dislodge them from their epithelial setting, such as bronchoscopy. If they are present at all in a sputum specimen, it is an indication of prior instrumentation, trauma, or severe cough. However, respiratory epithelial cells may also originate in the **nasal cavity** or **nasopharynx**; therefore, their presence in a specimen is not absolute insurance of origin from the lower respiratory tract.

Figure 19-7 Squamous cells in saliva. *A.* Superficial squamous cells of oral mucosal origin similar to those of cervicovaginal specimens. Note the single cell exhibiting moderate karyomegaly, and the bacterial background typical of saliva. *B.* A cluster of small squamous cells from deep layers of the epithelium, resembling the parabasal cells of cervicovaginal specimens. They are derived from an inflamed or ulcerated mucosa. The cells retain “intercellular bridges” and exhibit some cytoplasmic and nuclear hyperchromasia. *C.* Benign squamous pearl. Nuclei are small and innocent in appearance, and usually more numerous than in a malignant pearl. *D.* A plaque of anucleated keratinized cells suggestive of leukoplakia.

Ciliated Cells

Respiratory epithelium is readily recognized in cytologic material by the presence of **ciliated columnar cells** (Fig. 19-8A; see also Fig. 2-4).

Columnar cells may appear singly or in groups or clusters of cells, depending on how forcefully they have been dislodged. In brush specimens, **large numbers of bronchial cells** are commonly observed, sometimes forming clusters of considerable complexity (Fig. 19-8B), and sometimes also with **adherent reserve or basal epithelial cells** (Fig. 19-8C).

P.578

At the periphery of such clusters, normal ciliated cells may appear at a right angle to the main axis of the cluster, giving the impression of **feathering**, clearly **an artefact** induced by brushing (Fig. 19-8B).

Figure 19-8 Benign bronchial cells. *A.* Bronchial washing specimen showing dissociated normal ciliated columnar bronchial cells. The terminal plates to which the cilia are attached are well demonstrated in these optimally fixed cells. Nuclei may be relatively large and bulge out the bronchial cell (oil immersion). *B.* Bronchial brushing specimen showing bronchial cells in a cluster with some cells projecting out of the cluster to give a “feathering” appearance. *C.* Another cluster of bronchial cells in a brush specimen with adherent basal or reserve cells. *D.* Cuboidal bronchial cells derived from a peripheral bronchiole. Note one flat cell border.

The individual cells, derived from larger bronchi, are typically **cilia bearing and columnar in configuration**, measuring about 30 to 50 μm in length and 10 to 15 μm in width. **Much smaller, approximately square bronchial cells** with scanty cytoplasm and a flat surface, with or without cilia, derived from terminal bronchioles, are occasionally observed (Fig. 19-8D).

There is a prominent **linear thickening** or **flat terminal plate** at the luminal end of the columnar cell, **anchoring the cilia** (Fig. 19-8A). On close inspection, under very high magnification by light microscopy, the terminal plate is composed **of a series of confluent dots representing roots of the cilia** or **basal corpuscles**. In a well-executed Papanicolaou stain, the **cilia stain a distinct pink color**. While cilia may be damaged or lost, **the terminal plate is usually preserved** (Dalhamn, 1970). The opposite or basal end of the cell tapers off to terminate in a whip-like process representing the former point of attachment to the basement membrane.

Clusters or sheets of dislodged respiratory cells lying flat on the slide and **viewed from the luminal surface** have a **honeycomb** appearance, formed by the cytoplasmic borders of adjacent cells, not unlike endocervical cells (Fig. 19-9A).

The **cytoplasm** of the ciliated epithelial cell seen in profile is **homogeneous** and lightly **basophilic** or less commonly eosinophilic. Rarely, small mucus vacuoles may be observed. In the supranuclear cytoplasm of some bronchial cells, there are **granules of brown lipochrome pigment**, more commonly found in older patients and considered a “wear and tear” pigment (Fig. 19-9B). Rarely, the entire cytoplasm may eventually be filled with this pigment.

The **nuclei are usually very finely textured and oval in shape**, with their long axis corresponding to the long axis of the cell. Sometimes, the nucleus appears to be larger than the transverse diameter of the slender cell, resulting in a slight bulge at the level of the nucleus

(Figs. 19-8A and 19-10C). However, electron micrographs show that the nucleus is always surrounded by a rim of cytoplasm. Within most bronchial cell nuclei, there are usually one or two **small, but distinct, chromatin granules** and sometimes a **tiny nucleolus**. The **sex chromatin (Barr body)** may be readily recognized in females (see Fig. 2-4).

P.579

Figure 19-9 Benign bronchial cells. *A.* A plaque of bronchial cells seen on end has a honeycomb appearance much like endocervical cells. *B.* Lipochrome pigment in the cytoplasm of a bronchial cell. This is generally considered to be an aging phenomenon and has no diagnostic significance. *C.* Bronchial cell with a nuclear hole attributed to an artefact of preparation has no diagnostic significance. *D.* Dissociated single goblet cells in a bronchial brush specimen showing the supranuclear cytoplasm distended by multiple packets of mucin. (*D*: oil immersion.)

The **position of the nucleus** relative to the ciliated cell surface is variable, usually midway between the ciliated or luminal end of the cell and the tapered basal end. Chalon et al (1971) reported that in women of childbearing age, the position of the nucleus in the ciliated cells varies according to the time of the menstrual cycle, from a basal position in the proliferative phase of the cycle, to midposition after ovulation and to a position closer to the ciliated plate toward the end of the secretory phase. In men and postmenopausal women, he found that the position of the nucleus was always distant from the ciliated plate. Chalon et al attributed these variations to a changing mucopolysaccharide content of the cells during the cycle. To our knowledge, this has not been studied or confirmed by others.

The normal nuclei may also show **folds or creases** and sometimes, **intranuclear cytoplasmic inclusions**, or clear intranuclear “holes” (Fig. 19-9C). We find the latter to be more common in cancer cell nuclei. **Dense nuclear protrusions (nipples)** may also be observed in benign bronchial cells and are similar to those observed in endocervical cells at midcycle (see Chap. 8). Koizumi (1996) concluded that the “nipples” were a common nonspecific effect of mechanical forces during specimen collection or processing.

Goblet Cells

The mucus-producing **goblet cells** are less common than ciliated cells. They are approximately the same length but usually wider than the ciliated cells, with a **basally placed nucleus and**

distended supranuclear cytoplasm that is tightly packed with faintly basophilic tiny **vacuoles** representing packages of mucus. The much wider cytoplasm of these cells toward their luminal surface accounts for the “goblet” shape (Fig. 19-9D). The nuclei, located near the narrow, basal end of the cell are similar to those of ciliated cells, described above. Cilia are absent but **faint streaks of mucus** topping the broad luminal end of the goblet cell, **may superficially resemble cilia**, and can easily be differentiated by the absence of a terminal plate. If there is goblet cell hyperplasia as a result of asthma or chronic irritation, goblet cells will be present in increased numbers in brush specimens, as in Figure 19-9D. This finding may be of clinical significance and should be recorded.

Basal or Germinative Cells

The **basal or germinative cells** of the respiratory epithelium are the source of epithelial regeneration and normally form a single layer of cells on the basement membrane. In response to inflammation or injury, these cells may proliferate

P.580

and form several layers, resulting in **basal or reserve cell hyperplasia**. The significance of basal cell hyperplasia in the diagnosis of benign disease and neoplasia is addressed later in this chapter.

Figure 19-10 Pulmonary macrophages (dust cells). These cells come from the alveolar spaces, and are most abundant in BAL specimens. They are present in deep cough specimens of sputum, usually with a few leukocytes. There is variation in amount and staining of cytoplasm, which may have a yellowish color due to the presence of submicroscopic dust (*A*), or be densely crowded with phagocytized brown or black particles that obscure the nucleus (*B*). In the absence of phagocytosis, as illustrated in *C*, the cytoplasm may be finely vacuolated. Macrophages may be binucleated or multinucleated (*D*), and the reactive cells have multiple nuclei or prominent nucleoli. (*C,D*: oil immersion.)

Other Epithelial Cells

Other components of the **normal respiratory tract epithelium** such as **Clara cells**, neuroendocrine (**Kulchitsky**) cells, or **pneumocytes types I and II** are difficult or impossible to identify in clinical specimens of cytologic material without use of special cytochemical techniques (see Figs. 19-3D and 19-4C). **Hyperplastic or atypical pneumocytes type II**,

which may be seen in certain benign lung disorders, can enter into the differential diagnosis of cancer (see below).

Artefacts Induced by Delayed or Inadequate Fixation

If the fixation of the smears is delayed, there may be **drying artefact**, resulting in slight-to-moderate cellular and nuclear enlargement, loss of staining intensity and cellular detail, and often distortion of the bronchial cells with **loss of cilia, but usually preservation of the terminal plate**. **Artefacts of nuclear staining caused by drying** are generally well recognized, and typically manifest as nuclear enlargement, hypochromasia, and loss of nuclear detail. Drying artefact is most marked at the periphery of cell clusters and in isolated single cells, yet the basic uniformity of nuclear size and structure and the preservation of the nucleocytoplasmic ratio is still appreciated, supporting a benign diagnosis. The drying artefact may enhance the vacuolated appearance of the goblet cells' cytoplasm.

Mesothelial Cells

Although limited to the serosal surface of the lung, these cells are commonly observed in needle aspirates of peripheral lung lesions. They form flat clusters of cells that are separated by clear spaces or "windows," but may contain large nucleoli and be mistaken for cancer cells. For further discussion, see Chapters 20 and 26.

Alveolar Macrophages

The alveolar macrophages are of great importance in evaluating cytologic material from the respiratory tract. **Their**

P.581

presence confirms origin of the sample from pulmonary alveoli, hence the deeper portions of the respiratory tract, and sputum specimens are rarely of diagnostic value in their absence. Macrophages are most abundant in sputum specimens from cigarette smokers and in specimens from patients living in dusty environs, for example, from farmers. In BAL specimens, they are the predominant cell type, and present in abundance. The origin of these cells from bone marrow has been discussed above.

Macrophages appear most commonly as **spherical or oval cells** measuring from 10 to 25 μm or more in diameter. Their **cytoplasm**, usually amphophilic, may be abundant or limited in amount, basophilic or acidophilic, and usually contains a variable amount of phagocytized gray, brown, or black granular dust particles, hence the name **dust cells**, which is occasionally used. The dust particles may be below the resolving power of the microscope and simply lend a faint, usually yellowish color to the cytoplasm (Fig. 19-10A), or they may be numerous and dense, and completely obscure details of the cell structure (Fig. 19-10B). In smokers, as pointed out by Mellors (1957) and later by Roque and Pickren (1968), some of the granules fluoresce in ultraviolet light. In the absence of dust, the cytoplasm may contain fine vacuoles (Fig. 19-10C). As a rule, the periphery of the cells is sharply demarcated, but there may be one or several **cytoplasmic extensions or processes**. Walker and Fullmer (1971) described **nipple- or tail-shaped eosinophilic cytoplasmic extensions** of variable size, usually located at opposite ends of elongated macrophages. These cytoplasmic "tails" stain brilliantly eosinophilic, often in sharp contrast with the remainder of the cytoplasm. Such cells have been observed mainly in smokers and in people exposed to toxic inhalants (Frost et al, 1973), but their significance remains unknown.

The **nuclei of macrophages** vary in size and number but are generally round, oval, or kidney-shaped, about 5 to 10 μm in diameter, with fine, evenly dispersed chromatin and small nucleoli. Binucleation is common, as are **large multinucleated macrophages** (Fig. 19-10D), including

an occasional giant macrophage resembling Langhans' or foreign body giant cells. Kern et al (2003) found multinucleated cells with 3 to 10 nuclei in the majority of their patients, and at least a few multinucleated giant cells with more than 10 nuclei in BAL specimens from 10% of their patients. The latter were most common in sarcoidosis, but also viral infections, asbestosis, and various interstitial lung diseases including hard metal pneumoconioses. Kinoshita et al (1999) described bizarre macrophages of possible diagnostic value in the BAL specimens of two hard-metal workers.

The pulmonary macrophages, which are best studied in BAL specimens, not only phagocytize and remove respired dust particles that are not eliminated by the ciliated bronchial cells, they are the **primary defense against invading organisms** and are responsible for **removing dead or damaged cells and any foreign matter**. They are metabolically active cells that also ingest and **process antigens for presentation to T lymphocytes** and thus mediate a great many immunologic reactions. Activated macrophages **produce cytokines that recruit other inflammatory cells and growth factors** for fibroblasts and blood vessels (Abbas et al, 1991). Smoking adversely affects the pulmonary alveolar macrophages, as do a number of infectious and idiopathic disorders.

The functional activity of the alveolar macrophages can be estimated by a number of different techniques that include quantification of phagocytosis and immunocytochemical estimates of lysosomal enzyme activity—a marker of phagocytic cells. Like other monocytes, they express the **antigens CD-14 and CD-68**, and exhibit strong, diffuse, nonspecific esterase and acid phosphatase activity; 5'-nucleotidase is a marker of activated macrophages. Wehle and Pfitzer (1988) reported increased activity of nonspecific esterase in smokers and in persons with bronchial asthma.

Leukocytes

Polymorphonuclear leukocytes in small numbers are very common in cytologic specimens from the normal respiratory tract, especially in cigarette smokers. Kilburn and Mc-Kenzie (1975) pointed out that particulate matter in cigarette smoke recruits leukocytes to the bronchial tree. However, a finding of numerous polymorphonuclear leukocytes, particularly in the presence of necrotic material in an acutely ill patient, suggests a major inflammatory process such as **pneumonia or abscess** (Fig. 19-11A).

Eosinophils (Fig. 19-11B), or the elongated **Charcot-Leyden crystals** derived therefrom (Fig. 19-11C), suggest an **allergic process**, such as bronchial asthma.

Lymphocytes, singly or in pools, are a common finding in various inflammatory disorders; their presence in the appropriate clinical setting is consistent with **follicular bronchitis** (see below), but it must be remembered that they may be dislodged **from tonsillar tissue in subjects without disease**. In these benign conditions, there is typically a **mixture of mature small and medium lymphocytes** with scattered large reactive lymphoblasts and phagocytic macrophages (Fig. 19-11D). In lymphomas and leukemias, on the other hand, the lymphoid cells are more uniform. They present as small mature lymphocytes in the case of small-cell lymphocytic lymphoma or chronic lymphocytic leukemia, or as immature lymphoblasts or atypical mononuclear cells. Small-cell carcinoma is characterized by cells with irregular, hyperchromatic nuclei with coarse chromatin, nuclear molding, necrosis and streaks of DNA (see Chaps. 20 and 26). Tassoni (1963) stressed that pools of lymphocytes in small numbers may accompany lung cancer and that their presence warrants careful examination of the cytologic material. This has not been confirmed by others, and we have not found it useful. It should be noted that cigarette smokers have increased numbers of inflammatory cells in their airways and specifically, an **increased number of CD8+ (suppressor) T lymphocytes**, particularly in the presence of chronic obstructive pulmonary disease (Saetta et al, 1999).

Plasma cells are a frequent component of chronic inflammatory processes, particularly those involving the mouth and oropharynx.

Monocytes may be observed occasionally and are now known to be precursors of the larger alveolar macrophages.

P.582

Using fresh sputum, Chodosh (1970) found monocytes comprising 1% to 2% of the cells in specimens from patients with chronic bronchitis and chronic bronchial asthma.

Figure 19-11 Leukocytes. *A.* Polymorphonuclear leukocytes (PMNs), when present as the predominant cell type in a cough specimen or bronchial aspirate, and particularly if associated with necrotic cellular debris, indicate an acute inflammatory process such as pneumonia, bronchiectasis, or lung abscess. *B.* Eosinophils, if present in at least moderate number, are an indicator of an allergic inflammatory process and most commonly associated with asthmatic bronchitis. *C.* Needle-shaped Charcot-Leyden crystals may accompany marked eosinophilia. (Bronchial wash, high magnification). *D.* Pools of lymphocytes may be dislodged by bronchoscopy or after vigorous coughing from tonsillar tissues or lymphoid aggregates in lymphocytic bronchitis (follicular bronchitis). Mature lymphocytes are mixed with follicular lymphoblasts and histiocytes. They should not be mistaken for lymphoma or for SSC (see Chap. 20) (High magnification).

Mast cells have also been observed in material obtained by bronchial brushing (Patterson et al, 1972).

Megakaryocytes released from the marrow in vertebral or pelvic bones enter the systemic venous system and **traverse, or are sometimes trapped in capillaries of the lung** (Fig. 19-12A). In passing through the **pulmonary capillary bed, the megakaryocytes become elongated and are stripped of cytoplasm that is broken into platelets** (Melamed et al, 1966). Inevitably, some find their way into the alveolar air space, and on rare occasions, **they may be found in sputum, bronchial brushings, or FNA specimens of the lung** (Fig. 19-12B). They may be relatively well-preserved, with **multilobate nuclei** and abundant cytoplasm, but more commonly are only **sausage-shaped nuclei**.

Other Nonepithelial Cells

Takeda and Burechailo (1969) reported the presence of **smooth muscle cells in sputum** of a patient who had the pulmonary form of Wegener's granulomatosis with bronchial ulceration. They pointed out the difficulty in correctly identifying these cells. We have seen smooth muscle cells on occasion in bronchial brush specimens, presumably due to vigorous brushing (Fig. 19-12C).

Noncellular Endogenous Material

Curschmann's Spirals

Curschmann's spirals are **casts of inspissated mucus**, derived from and shaped by the lumens of small bronchi. The characteristic coiled appearance of the spirals, with a **dark central axis and a translucent periphery**, allows easy recognition (Fig. 19-13A).

The presence of Curschmann's spirals has long been considered diagnostic of **chronic bronchitis** or **asthma**, diseases in which there is an increased number of goblet cells and increased secretion of mucus. However, Curschmann's spirals are likely to be found in patients with goblet cell hyperplasia or metaplasia and increased mucus secretion of any cause. Walker and Fullmer (1970) documented that

P.583

over 90% of **asymptomatic cigarette smokers** have such spirals in their sputum. Plamenac et al (1972) found Curschmann's spirals in the sputum of former cigarette smokers for 6 years after cessation of smoking. There was no correlation found between the daily consumption of cigarettes and the number of spirals per specimen.

Figure 19-12 Uncommon cell types. *A.* **Megakaryocyte** trapped in alveolar capillary of lung. *B.* Megakaryocyte with multilobulated nucleus and abundant, ragged cytoplasm seen in an FNA of lung. Most megakaryocytic nuclei are stripped of cytoplasm as they pass through the alveolar capillaries. *C.* Bronchial brush specimen with a cluster of spindly **smooth muscle cells** that have elongated nuclei with rounded ends (*A*: Oil immersion).

Inspissated Mucus

Inspissated, amorphous mucus may form **small, dark staining, structureless bodies (blobs)** that occasionally have the **size and shape of nuclei** (Fig. 19-13B,C). We have observed situations where they were **mistaken for nuclei of cancer cells**, particularly if they happened to overlay a cell. Close attention must be paid to the absence of any internal structure in the

blobs of mucus.

Corpora Amylacea

Corpora amylacea are **spherical, translucent structures** that may be found in alveoli of people who have had previous episodes of pulmonary edema. Such structures, which in all likelihood represent a condensation of proteins, may be observed on occasion in sputum (Fig. 19-13D,E). Schmitz and Pfitzer (1984) described very similar “acellular bodies” in 1% of sputum specimens from 70 patients with a **variety of chronic pulmonary disorders**, including one with adenocarcinoma. They observed an association of the “acellular bodies” with Curshmann's spirals and correlated them with similar structures found at autopsy in alveolar spaces and dilated ducts of bronchial glands.

Amyloid

Amyloid was observed in irregular, amorphous fragments by Chen (1984) and by Neifer and Amy (1985) in the bronchial brushings of patients who had documented tracheobronchial amyloidosis. The homogeneous, waxy appearance of the fragments should raise suspicion of amyloid, and their apple-green birefringence under polarized light after Congo red staining establishes the diagnosis (Fig. 19-14A,B). Neifer and Amy noted the **similarity of such fragments to corpora amylacea**, which may also stain with Congo red, but are spherical or oval structures that lack the apple-green birefringence of amyloid. Other cases of pulmonary amyloid nodules diagnosed by aspiration biopsy were reported by Tomashefski et al (1980) and Vera-Alvarez et al (1993). We have not seen such a case in cytologic material.

Pseudoamyloid

We observed a case of pseudoamyloid in a 73-year-old patient with an endobronchial lesion. Fragments of **faintly fibrillar, eosinophilic material indistinguishable from amyloid were observed in bronchial brushes** and in the cell block (Fig. 19-14C), which also contained a small fragment of bronchial epithelium. The material **failed to give the Congo red reaction** and was therefore classified as pseudoamyloid, a rare event in the lungs usually associated with light-chain deposits in the presence of multiple myeloma (Kijner et al, 1988; Stokes, et al, 1997).

Calcific Concretions

Small calcific concretions may be observed in sputum of people with **chronic pulmonary diseases, especially tuberculosis**. They also suggest the possibility of **alveolar microlithiasis**, a rare disorder of unknown etiology in which there are numerous calcific deposits within the alveoli that interfere

P.584

with respiratory exchange. The diagnosis may be suspected by radiologic findings that are often striking in patients with minimal symptoms (Brandenburg and Schubert, 2003) and can be confirmed by finding the calcospherites in sputum or bronchoalveolar washings (Fig. 19-15A,B). Unlike corpora amylacea, they are hard and crystalline and may fragment. They must be differentiated from **calcium oxalate crystals**, which are sometimes associated with and should suggest the possibility of fungal infection with aspergillus (see below).

Figure 19-13 Acellular components of intrinsic origin. **A. Curschmann spiral** in sputum. Spiral-shaped inspissated mucus cast of a bronchiole. Note the darker staining central core with lighter staining edges. **B,C. Mucus blobs.** The mucus has condensed into a round droplet that is dark staining centrally and lighter staining peripherally, mimicking a cancer cell nucleus and cytoplasm. The “nucleus” is structureless. **D,E. Coropora amylacea.** Spherical, translucent, structureless condensates of protein, usually associated with pulmonary edema of some duration. (*C,E*: oil immersion.)

Exogenous Foreign Material

Ferruginous Bodies (Asbestos Bodies)

Exposure to some forms of asbestos in respired air induces **pleural and pulmonary fibrosis**, risk of **malignant mesothelioma**, and, in cigarette smokers, a five- to tenfold increased risk of **lung cancer** (see Chap. 26). The inhaled uncoated asbestos fibers, measuring less than 1 μm in diameter and about 50 μm or more in length, are translucent and scarcely visible (Fig. 19-16A). In the lung, they become coated with protein and iron (hence ferruginous), giving them a characteristic **golden-brown, segmented or beaded bamboo shape with knobbed or bulbous ends** (Fig. 19-16B). The fibers are sometimes partially enveloped by a macrophage, as was first described by Frost et al (1973). The coated ferruginous bodies of asbestos fibers measure from 5 to 200 μm in length and 3 to 5 μm in diameter. The larger fibers are removed by bronchial ciliary action. Asbestos exposure is most common among certain construction, shipbuilding, and

P.585

industrial workers, and in recent years, the workers involved in demolition of older buildings in which asbestos was used for insulation. **Routine sputum samples from individuals exposed to asbestos may contain the characteristic ferruginous bodies.** However, they

are more abundant and **more easily demonstrated in BAL** specimens, and can be found in those specimens even in patients without known exposure to asbestos. There is a correlation between the number of ferruginous bodies in BAL samples and in lung tissue (Teschler et al, 1994), and the presence of large numbers of ferruginous bodies in lavage specimens (>1 per 10^6 cells) is indicative of considerable asbestos exposure (Roggli et al, 1986).

Figure 19-14 Amyloid. *A.* Amyloid involving lung, pale eosinophilic acellular material. *B.* “Apple green” birefringence of amyloid in polarized light after **Congo red stain**. *C.* **Pseudoamyloid** in a cell block section of tissue recovered by bronchial brush, resembling amyloid but not birefringent. Fragments of amyloid have been described in bronchial specimens (see text).

Figure 19-15 Pneumoliths in bronchial irrigation specimen from a 73-year-old woman with chronic lung disease. *A.* Pneumoliths are small, generally round laminated microcalcific bodies. *B.* Broken pneumolith (oil immersion).

Rosen et al (1972) examined digests of lung tissue in surgical and autopsy specimens and documented the presence of small numbers of typical asbestos ferruginous bodies in the lungs of virtually all people living in an urban area. They are most commonly present in the lower lobes. Using Smith and Naylor's method (1972), Bhagavan and Koss (1976) documented a dramatic increase

in the lung content of asbestos bodies over the three decades from 1940 to 1972. Surprisingly high counts of asbestos bodies were found without evidence of lung disease in digests of sputum and lung tissue from young children and juveniles as well as adults. Thus, the **presence of asbestos bodies in sputum does not necessarily imply asbestos-related disease**, and must be interpreted with appropriate caution after correlation with clinical and radiologic findings.

Figure 19-16 Acellular components of sputum or bronchial cytology of extrinsic origin. A,B. Ferruginous bodies. These are **asbestos bodies**, but mineral fibers of diverse origin can be similar in appearance. The fiber itself is thin and almost transparent (A), but has a golden-yellow coating of protein with iron (B), hence the name *ferruginous*, which is generic for all such fibers. Macrophages in a futile attempt to phagocytize and remove an asbestos fiber.

Asbestos bodies may be found in FNAs of lung lesions. In a series of 1,256 transthoracic FNAs, Leiman (1991) found them in 57 specimens from 55 patients. They were an incidental finding in all cases; in none was asbestos-induced fibrosis alone responsible for the lung mass aspirated, except for one patient with a mesothelioma.

Asbestos fibers are by far the most common substrate of ferruginous bodies, but **other mineral fibers may have a similar appearance** (Churg and Warnock, 1981; Mazzucchelli et al, 1996). Some of the nonasbestos ferruginous bodies are distinguished by a **fibrous core that is opaque or colored** rather than clear, and some **may be curved or branched** rather than straight. Rosen et al (1973) reported such “atypical” branching or segmentally thickened fibers in digests of lung and fibrous pleura.

Undigested Food Particles

Particles of food are commonly observed in sputum, particularly from patients with poor oral hygiene and must be recognized as contaminants.

Material of Plant Origin

Vegetable matter is one of the most common contaminants in sputum specimens. **The cells comprising fragments of plant tissue** have a characteristic **heavy cellulose cell wall** and are easily identified (Fig. 19-17A), but isolated plant cells that have lost the cellulose wall (Fig. 19-17B,C) may be confused with cancer because of their large dark nuclei. They are readily recognized after some experience, even in the absence of a heavy cellulose membrane, because of the **homogeneous staining of plant cell nuclei** and the frequent presence of **refractile, pigment granules within the cytoplasm**. Weaver et al (1981) have provided a

detailed study of plant cells in sputum.

Meat Fibers

Meat fibers composed of striated muscle are easily recognized by the presence of cytoplasmic cross-striations and peripherally placed nuclei. Smooth muscle cells are less commonly seen. They are elongated spindle cells with centrally placed ovoid nuclei and are without striations. Neither muscle cells, fat cells, cartilage cells, nor the occasional cells of epithelial origin that are found in undigested food have cellulose cell membranes.

Pollen

Sputum may contain pollen of plant origin, recognized as **spherical or oval, dark yellow or brown** structures of variable sizes, rarely smaller than 25 to 30 μm in diameter and provided with a characteristic thick, refractile cell wall (Fig. 19-17D). They are more commonly found in the spring and summer, and particularly if the processing laboratory is exposed to outside air (see Chap. 8).

Other Contaminants

The brown, septate, boat-shaped fungal organisms of ***Alternaria species*** (Fig. 19-18A) are present in earth and water and are a frequent contaminant. Radio et al (1987) pointed out that *Alternaria* has been found in bronchioalveolar lavage material and may rarely be a pathogen.

Small **nematodes** (Fig. 19-18B,C), also from tap water, may be found in sputum as in other cytologic specimens. They must be differentiated from ***Strongyloides stercoralis*** (see below). Usually, it is clear from the clinical setting that they are contaminants, but if there is doubt, repeat specimens should be obtained with care to prevent contamination.

Copepods, another contaminant of tap water (Fig. 19-18D),

P.587

have been reported to cause disease on rare occasions (Van Horn et al, 1992).

Figure 19-17 Vegetable (plant) cells. A. Plant cells in flat fragments with thick transparent cellulose walls. The **cellulose walls**, which do not stain with either Papanicolaou or hematoxylin/eosin stains specifically identify vegetable cells. B,C. Poorly preserved single vegetable cells may have lost their cellulose cell wall but are still identified by homogeneous staining nuclei and often by **pigmented granules in the cytoplasm**. D.

Pollen, a common air contaminant. Their structure is variable depending on the flower or plant from which they come, but they are usually easily recognized.

Abundant bacterial or fungal growth in a poorly preserved specimen with minimal or no inflammatory infiltrate suggests that the specimen was left standing for many hours at room temperature without fixative, and the organisms present must be disregarded.

BENIGN CELLULAR ABNORMALITIES OF THE RESPIRATORY TRACT

Various noncancerous processes within the respiratory tract may affect the cytologic makeup of smears. **Many such disorders have common cytologic findings** and cannot be diagnosed with confidence on cytology grounds alone. **Knowledge of the roentgenologic and clinical findings is always desirable and often essential for specific classification of a pathologic process.** In cases of inflammation, bacteriologic studies are needed, as is a careful search for viral cytopathic changes and the presence of fungi or parasites. Even without specific classification, however, knowledge of the degenerative and reactive cytologic changes that accompany inflammatory and other benign pathologic processes is essential if one is to avoid a false diagnosis of cancer.

Benign disorders of the respiratory epithelium may be manifested by abnormalities of:

- Respiratory bronchial epithelium
- Squamous epithelium
- Alveolar epithelium, particularly pneumocytes type II
- Pulmonary macrophages

Benign Abnormalities of Bronchial Epithelium

Abnormalities of Ciliated Cells

Cytologic techniques have been applied extensively to studies of the respiratory epithelium in various clinical settings. The information derived therefrom carries with it major diagnostic implications.

Acute Injury

The **loss of cilia and terminal plate** is a common response of the respiratory epithelium to acute injury. It was demonstrated experimentally in bovine lung exposed to cigarette smoke and viral infection (Sisson et al, 1994), and may be observed in thermally injured patients who have inhaled

P.588

hot gases (Ambiavagar et al, 1974). In burn victims with great exposure to hot gases and smoke, there is extensive necrosis of respiratory epithelium followed by squamous metaplasia (see below), and severe degenerative changes including mitochondrial calcium deposits in surviving bronchial cells (Drut, 1998).

Figure 19-18 Contaminants. *A. Alternaria species*, a contaminant from air or tap water, is a genus of fungi and readily recognized by its shape and pigmented, segmented structure. *B, C. Nematodes*, also present in tap water, may be a contaminant and mistaken for pathogenic microfilaria. Compare with Figure 19-52B. Usually, it is clear from the clinical setting, that they are a contaminant. *D. Copepod*, a contaminant of tap water, rarely reported to cause infection. (*D*: High magnification; *C*: oil immersion.)

Chalon et al (1974) reported that in patients under anesthesia, after 3 hours inhalation of dry anesthetic gases, 40% of the respiratory epithelial cells showed loss of cilia, changes in cell configuration and staining, and some nuclear pyknosis. Such damage was preventable by humidification.

Nonspecific Abnormalities of Bronchial Cells

Multinucleation of Bronchial Cells

Multinucleation of bronchial lining cells may result from a failure of cell division after nuclear replication and division, and involve **single well-differentiated ciliated cells** (Fig. 19-19A); or it may be the result of cell fusion with formation of **true syncytia** (Fig. 19-19B). The number of nuclei in single cells may vary from 2 or 3 to about 20, whereas in syncytia, the number varies from few to over 100. The **nuclei** within the multinucleated cells are **small, regular, and equal in size**. Since it is known that certain viruses may produce cell fusion, and thereby true syncytia, the **possibility of a viral infection** should be considered when syncytial multinucleation is observed. **However, in most cases, multinucleated bronchial cells are a nonspecific reaction to injury.** They have been observed within 48 to 72 hours after a variety of traumas, including bronchoscopy, x-ray therapy, and exposure to fumes. They should not be confused with tumor cells, with which they have no common traits.

Cell and Nuclear Enlargement

Occasional individual ciliated bronchial cells may be considerably larger than others (**cytomegaly**), sometimes **twice or more their normal size**, with **proportionally enlarged nucleus (karyomegaly)**, usually containing a **single prominent nucleolus or multiple small nucleoli** (Fig. 19-19C). Here again, the cilia, or at least the terminal plates, are often well preserved. Such cells appear under a variety of circumstances, and like multinucleation and nucleolar enlargement (see below), they are a nonspecific response of the respiratory

epithelium to various forms of injury. They may be observed after even **minor trauma** such as repeated bronchoscopies or **bouts of severe coughing**, and also in **inflammatory processes** such as **bronchitis, bacterial or viral pneumonia, or tuberculosis**, but also in cancer.

P.589

Figure 19-19 Nonspecific bronchial cell atypias. A. Multinucleation. B. Syncytia. C. Cytomegaly and karyomegaly. D. Nucleolar prominence in otherwise bland and uniform bronchial cells. The cells are cuboidal, with smoothly contoured round or oval nuclei and delicate chromatin. They are separate or in flat plaques, unlike the cells of adenocarcinoma, which cluster in groups of overlapping cells. (C: oil immersion.)

Cohen et al (1997) reported a 9-year-old boy with Ataxia-Telangiectasia (AT) who had aneuploid karyomegaly of bronchial cells obtained by bronchial brushings. They suggested that the finding of aneuploidy might be related to the known increased risk of cancer in this genetic disease. However, the child had had recurrent respiratory infections and was suffering from severe chronic obstructive lung disease; it is not clear whether the karyomegaly was due to the genetic defect of AT or simply reactive to injury and infection.

Nucleolar Enlargement

Under a broad variety of circumstances, **benign bronchial cells may display prominent single or multiple nucleoli**. The affected cells are either **normal** in size and shape or the cells are **more cuboidal and slightly enlarged**. Those that **retain their cilia or at least their terminal bar** should not be mistaken for cells of adenocarcinoma (see Chap. 20). Others having lost cilia and terminal bar are undergoing squamous metaplasia or repair (see below).

Ciliocytophthoria

Under this term, Papanicolaou (1956) reported a unique type of destruction of ciliated bronchial cells occurring in some inflammatory conditions of the lung, especially viral pneumonia. The distal ciliated portion of the cells is pinched off, resulting in the formation of **anucleated ciliated tufts** and **nucleated cytoplasmic remnants** (Fig. 19-20A,B). **Nuclear degeneration**, resembling apoptosis, and the presence of **cytoplasmic eosinophilic inclusions** of various sizes (Fig. 19-20C) complete the picture. Papanicolaou initially

associated **ciliocytophthoria** (CCP) with bronchogenic carcinoma; he reported one case in which CCP preceded the appearance of tumor cells by 10 months. However, evidence has now shown that CCP is not a precancerous event, but a form of cellular degeneration often associated with viral infections and possibly due to adenovirus or other viral pneumonitis (see below).

Lipochrome Pigmentation

With aging, there is an accumulation of lipochrome pigment in bronchial epithelial cells, the so-called “wear and tear” pigment (see Fig. 19-9B). As already described it has no diagnostic significance. The pigment is brown, faintly granular and accumulates first in the supranuclear cytoplasm of intact, otherwise normal bronchial cells.

Immobile Cilia Syndrome

Abnormal cilia are common in bronchial epithelial cells of cigarette smokers and in patients with neoplastic and a number of chronic nonneoplastic diseases of lung (McDowell et al, 1976a).

P.590

However, the **immobile cilia syndrome** is a rare congenital **abnormality of cilia** caused by absence of dynein arms or defective radial spokes resulting in chaotic, uncoordinated beating of cilia. Young children with this disease suffer illnesses resulting from a **deficiency of mucociliary transport** (Afzelius, 1976, 1981). They typically present with recurrent respiratory infections and sinusitis. The classic form of this syndrome, described by Kartagener in 1933, and now known as the **Kartagener syndrome**, comprises **bronchiectasia, chronic sinusitis, and situs inversus**. Because spermatozoan flagella are also affected, sterility in males has been noted. The disorder can be diagnosed only by electron microscopy (see Chap. 2). Transposition of ciliary microtubules is another cause of impaired motility of cilia (Sturgess et al, 1980). Moreau et al (1985) reported that **cytologic samples from bronchial and nasal brushings** may be suitable for electron microscopic examination to determine if the ciliary structure is deformed; however, it should be noted that in some cases, ciliary abnormalities in respiratory epithelium may be a result rather than a cause of chronic or repeated respiratory infections.

Figure 19-20 Ciliocytophthoria (CCP). Sputum specimen from a young woman on the second day of her illness with a viral pneumonia. A. The ciliated cytoplasmic end of a

bronchial cell with pyknotic nucleus is pinched off. *B.* In the same specimen, there were detached anuclear ciliated cytoplasmic tufts and cell fragments with pyknotic nuclei. *C.* Degenerating cell with eosinophilic intracytoplasmic inclusion. (*A-C*: High magnification.)

Abnormalities of Goblet Cells

In chronic inflammatory processes, as for example in chronic bronchitis, bronchiectasis, and asthma, there may be hyperplasia of goblet cells in bronchial mucosa and increased mucus secretion. Sputum, bronchial aspirates, and washings from such patients contain an **increased number of goblet cells**, some of which may be significantly **larger than normal**. This finding has no other known significance.

Benign Proliferative Processes in Respiratory Epithelium

Benign proliferations of the respiratory epithelium may occur as a reaction to injury, usually an inflammatory process, and cause **papillary hyperplasia, basal (reserve) cell hyperplasia or squamous metaplasia of bronchial mucosa**. These processes can have a major impact on the cytology of the respiratory tract.

Papillary Hyperplasia of the Respiratory Epithelium (Creola Bodies)

Histology

Hyperplastic respiratory epithelium is most commonly observed in chronically inflamed, dilated bronchi, that is, **bronchiectasis**, but may be seen in other **chronic pulmonary disorders, in bronchial asthma, and in viral pneumonitis**. The mucosa **undergoes folding and formation of papillary projections** (Fig. 19-21A). The **epithelial surface** of these hyperplastic areas is composed of **normal ciliated and goblet cells**, with deeper layers of smaller intermediate or basal epithelial cells. The individual epithelial cells may have visible nucleoli but are generally uniform, coherent, and do not show the nuclear hyperchromasia,

P.591

coarse chromatin, or very prominent nucleoli of adenocarcinoma (see Chap. 20).

Figure 19-21 Creola bodies. *A* Hyperplastic bronchial mucosa in bronchiectasis, a source of apillary fragments of bronchial epithelium in pulmonary cytology specimens. *B, C.*

Fragments of hyperplastic reactive bronchial epithelium (Creola bodies) that in *C* are from a 28-year-old patient with AIDS who has had chronic lung infections. The most peripheral cells have a smooth surface configuration and are recognizable as bronchial cells; deeper in the cluster are intermediate or basal cells. *D*. Creola body surfaced by mucin-secreting cells. Creola bodies should not be mistaken for papillary carcinoma.

Cytology

The hyperplastic bronchial mucosa sheds **spherical or ovoid papillary clusters of bronchial cells**. As in histologic sections, the **surface is formed of well-preserved respiratory epithelial cells with cilia or terminal plates**, whereas the core of these clusters is composed of uniform small cells (Fig. 19-21B,C). Cilia are not always well preserved. When the hyperplastic mucosa is rich in **goblet cells**, they will be displayed in the surface layers of the exfoliated clusters (Fig. 19-21D). Of some importance is the occasional presence of **tiny, usually single nucleoli** within the nuclei of cells lining the papillae. They should not be mistaken for the much larger nucleoli of adenocarcinoma (see Chap. 20). These cell clusters were first described as a possible diagnostic pitfall by Koss and Richardson in 1955. They were subsequently called **Creola bodies** by Naylor (1962), who named them for a patient with asthma who produced sputum specimens with numerous such clusters. Naylor warned against misinterpreting these papillary cell clusters as papillary adenocarcinoma. He and Railey (1964) identified the papillary clusters in sputa of 42% of asthmatic patients, frequently present during the asthmatic attack. Folded fragments of mucosa dislodged by endoscopic procedures may be mistaken for Creola bodies.

A large number of such papillary clusters may be observed in cytologic specimens from adults with acute respiratory disorders of viral etiology, or from infants and children with viral pneumonitis or acute respiratory distress syndrome (ARDS) (see also Fig. 19-32). In those patients, there is usually a prompt return to normal after the acute illness has subsided. Sheets of bronchial cells originating in hyperplastic bronchial epithelium have been reported in **Wegener's granulomatosis** (Hector, 1976).

Of prime importance in differentiating these papillary clusters of cells from the somewhat similar cell clusters that may be observed in well-differentiated bronchioloalveolar adenocarcinoma are:

- The presence of cilia or a terminal plate on the free surface of the outermost cells
 - The presence of normal goblet cells on the free surface of the cluster, indicating benign disease
-
- Nuclei of normal size and configuration, whereas in adenocarcinomas they are larger and are provided with large nucleoli

P.592

Further points of differential diagnosis are discussed in Chapter 20.

Basal Cell Hyperplasia

Histology

The small basal or germinative cells situated next to the basement membrane in the respiratory epithelium are normally unobtrusive and may escape the attention of a casual observer (see the section on the Respiratory Epithelium above). Basal (or reserve cell) hyperplasia is the result of **abnormal multiplication of these basal cells**, which can form **many layers occupying a substantial portion of the thickened epithelium**. Usually, the surface of the altered

epithelium is topped with a layer of ciliated respiratory epithelium and goblet cells, confirming that the process of epithelial maturation is preserved (Fig. 19-22A). Because the basal cells are small and their nuclei occupy much of the total cell volume, the **epithelium may have a disturbing hyperchromatic appearance. Unlike small-cell carcinoma, however, the benign hyperplastic basal epithelium is composed of uniform cells in an orderly arrangement.** The problem of recognition occurs only if the maturing surface of the epithelium is lost.

Figure 19-22 Basal cell hyperplasia of bronchial epithelium. *A*. Histologic section of bronchial mucosa showing basal cell (reserve cell) hyperplasia. Note that there are several layers of basal epithelium. *B, C*. Basal cell hyperplasia in bronchial brush specimens. The cells are small and generally uniform with scanty cytoplasm and relatively large hyperchromatic nuclei. They differ from small cell carcinoma in that the cells are coherent and nuclei are uniform and smoothly contoured without necrosis or molding, and without evidence of active proliferation. Often, there is either a straight edge to the cluster of cells, or some cells show evidence of maturation (see Chap. 20). *D*. Basal cells are best visualized when present in loose clusters of cells. At high magnification, they have scanty cytoplasm and uniform, smoothly contoured nuclei with dark staining but finely textured chromatin and a small nucleolus. They must be differentiated from large-cell lymphoma and SSC, discussed in Chapter 20. (*C, D*: oil immersion.)

Basal cell hyperplasia is a nonspecific response of the respiratory epithelium, usually induced by chronic inflammatory processes. Affected bronchi may be found in **chronic bronchitis** and **bronchiectases**, especially with **bronchiectatic cavities**, in **tuberculosis** and in other forms of chronic inflammation including **organizing pneumonia** and **mycotic infections**, particularly with mycetomas. However, such changes may also occur in bronchi adjacent to bronchogenic carcinoma.

Cytology

Normally, the basal cells are firmly adherent to the basement membrane and therefore exceedingly uncommon in sputum.

They are more commonly seen in specimens obtained by instrumentation in which there is

forceful disruption of the epithelium, and they usually form coherent clusters of various sizes made up of small rounded or polygonal cells (Fig. 19-22B-D). Several such clusters of cells are often present in the same specimen, and sometimes in the company of ciliated cells that are also dislodged in the course of bronchial intubation or other manipulations. The latter may have been damaged in the process or destroyed by disease and atypical in appearance.

These **clusters of small basal cells with dark nuclei and scanty cytoplasm** are always disquieting, even to an experienced observer, as they **may suggest a small-cell malignant tumor**. Their interpretation becomes particularly difficult when the pathologist is pressured to make a diagnosis in cases suspected of carcinoma clinically or radiologically. Following are the characteristics of bronchial basal cells that allow their correct classification and diagnosis:

- The cells, as a rule, appear in **clusters that are tightly packed** and show little if any tendency to dissociate (see Fig. 19-22B). One edge of the cluster may be straight, presumably where detached from the basement membrane.
- The **cells are small**, somewhat larger than leukocytes, with relatively prominent but quite **uniform dark, round, or oval nuclei**. Nucleoli may be observed, but are tiny and inconspicuous (Fig. 19-22D). Cytoplasm is scanty and basophilic. At the periphery of at least some of the clusters, one usually finds larger cells with very similar nuclei but more cytoplasm, suggesting differentiation toward columnar or metaplastic squamous cells.
- Nuclear molding by adjacent cells, characteristic of small-cell (oat cell) carcinoma does not occur in the clusters of benign reserve cells. Other nuclear abnormalities observed in small-cell malignant tumors are absent (see Chap. 20).

The problem of diagnosis is compounded if the **clusters of small basal cells are loosely structured**, rather than compact, and may include cells with somewhat larger nuclei. (Fig. 19-22C-D). **Such instances of basal cell hyperplasia may be very difficult to differentiate from small-cell carcinoma**, and have been seen in association with carcinoma elsewhere in the bronchi. For other points of differential diagnosis, which includes carcinoid and malignant lymphoma, see Chapter 20.

Squamous Metaplasia

Squamous metaplasia is a common reaction to injury in the bronchus and is defined as the **replacement of respiratory mucosa by squamous epithelium**. It can be limited in extent or diffuse and implies the capability of germinative basal cells to form squamous epithelium under abnormal circumstances. Both basal cell hyperplasia and squamous metaplasia result from chronic irritation of the respiratory tract and may be considered a means of defense or adaptation of the mucosa to abnormal circumstances. Whether squamous metaplasia may or may not revert to normal ciliated epithelium is not known; possibly the process is reversible in its early stages, but cytologic studies suggest that well-developed squamous metaplasia persists relatively unchanged for many years (Grunze, 1958).

The **mechanism of formation** of squamous metaplasia of the bronchus is uncertain. While it may fairly rapidly follow massive damage or loss of respiratory epithelium, for example, in bronchopulmonary dysplasia of newborns (see below), in most cases, it appears to be a more gradual process of progressive squamous differentiation.

Some histologic studies have implicated squamous metaplasia as **a step in the development of squamous lung cancer**. There is increased frequency of squamous metaplasia in cigarette smokers and with advancing age, paralleling an increased risk of lung cancer. Some observers also report increased atypia of squamous metaplasia in cigarette smokers with increasing number of cigarettes smoked (Kierszenbaum, 1965; Nasiell, 1966; Saccomanno et al, 1970).

However, the relationship of squamous metaplasia to squamous lung cancer has been brought into question by the frequent finding of squamous metaplasia without lung cancer (see below), and by our own studies of cigarette smokers in whom orderly squamous metaplasia is found in mainstem and lobar bronchi, whereas early lung cancer most often begins more distally in segmental bronchi. In the very early lung cancers that we have studied, squamous carcinoma in situ of the bronchus has not necessarily been associated or in continuity with squamous metaplasia. On the other hand, **atypical squamous metaplasia is a potential precursor of bronchogenic squamous carcinoma** (see Chap. 20).

Squamous metaplasia is a common finding in patients free of cancer. For example, Spain et al (1970) found squamous metaplasia in the bronchial tree of 50% of 500 healthy adults of all ages who died accidentally. Cytologic evidence of metaplasia was reported by Plamenac et al in wind instrument players (1969), commonly in men past the age of 65 (1970), and in former cigarette smokers (1972). Good et al (1975) reported atypical metaplastic changes in the sputum of users of pressurized spray cans. These cytologic reports, not supported by histologic evidence, should be considered with some caution. **Histologically documented squamous metaplasia has been observed in a broad spectrum of benign inflammatory lung disorders**, including chronic bronchitis, bronchiectasis, lung abscesses, and granulomatous inflammations. Squamous metaplasia may also occur in areas of pulmonary infarcts and after radio- and chemotherapy. Therefore, **squamous metaplasia of the bronchial epithelium without atypia must not be regarded as a precancerous lesion.**

Squamous metaplasia has never been implicated in the development of bronchiolar or adenocarcinoma of the lung, or of small-cell (oat cell) carcinoma, both of which are also attributable to cigarette smoking.

Histology

As noted, squamous metaplasia is seen in mainstem and lobar bronchi. In the earliest evidence of squamous metaplasia, the respiratory columnar epithelium is replaced by a superficial layer of flattened cells in association with basal cell hyperplasia. This may involve only limited areas of bronchus, usually

P.594

at bifurcation sites, or progress to extensive complete replacement of respiratory epithelium by nonkeratinizing squamous epithelium (Fig. 19-23A). Very often, the squamous epithelium lining the surface of the bronchus is not "pure" but includes scattered respiratory cells, or metaplastic squamous cells with intracellular mucin. Other cells that are only partially differentiated may retain their cuboidal or columnar shape and a flat free surface, but lack cilia and a terminal bar. These features of the metaplastic epithelium are important indications of their common origin with respiratory epithelium from undifferentiated reserve cells.

The frequent coexistence of basal cell hyperplasia with squamous metaplasia suggests that the former precedes the latter, but whether this is always the case is open to conjecture. The two processes can be seen side by side in cytologic material.

Cytology

Cells in **sputum** that originate from orderly squamous metaplasia of the bronchus may be difficult or impossible to differentiate from the normal squamous cells of the mouth, pharynx, or larynx. In **bronchial washings, aspirates, and brush specimens**, however, the presence of squamous cells can be explained only by squamous metaplasia (excluding the common occurrence of contamination from the upper respiratory tract). Squamous metaplasia is typically represented by **small squamous cells, often in clusters or sheets of cells with eosinophilic cytoplasm, resembling the parabasal cells of squamous epithelium or**

showing partial differentiation to respiratory epithelium. The metaplastic cells **usually adhere well to each other and may have nuclei that are vesicular and open** (Fig. 19-23B,C) or hyperchromatic (Fig. 19-23D). As in histologic sections, the bronchial origin of metaplastic squamous epithelium is best demonstrated when the periphery of the cluster is composed of cuboidal or columnar cells with a straight edge or terminal plate (Fig. 19-23B). The cytologic features of squamous metaplasia of bronchial epithelium are not unlike squamous metaplasia of endocervical epithelium (see Chap. 10), in which the relatively small cuboidal cells have an angular configuration and hyperchromatic nuclei (Fig. 19-23D). Significant cytologic abnormalities resulting from squamous metaplasia of the trachea following intubation or laryngectomy are discussed below.

Figure 19-23 Squamous metaplasia of bronchial epithelium. *A*. Histologic section of bronchus showing squamous epithelium completely replacing the respiratory epithelium in an example of fully developed mature squamous metaplasia. *B,C*. Squamous metaplasia in a cough specimen of sputum. The cells are cuboidal, with moderately abundant eosinophilic or amphophilic cytoplasm. They form loosely coherent flat plaques, much like endocervical squamous metaplasia with usually one straight edge. *D*. Bronchial brush specimen showing squamous metaplasia. The cells form a loosely coherent flat plaque of cuboidal, relatively small cells with amphophilic or eosinophilic cytoplasm. Alveolar macrophages and a mature squamous cell are present for comparison.

P.595

Tracheitis Sicca

Squamous metaplasia is part of the repair process after injury to bronchopulmonary tissues, and in some circumstances, there may be significant atypia. Particularly severe atypias of squamous cells have been described in the trachea and tracheobronchial aspirates of patients with prolonged tracheal intubation and patients with **tracheitis sicca** (dry tracheitis) who have permanent tracheostomies following laryngectomy for carcinoma. They are at high risk of developing a new primary carcinoma of lung, and we have recommended monitoring them at regular intervals by tracheal aspiration cytology (see Chap. 20). The dry and constantly irritated mucosa of the upper trachea undergoes squamous metaplasia, sometimes with keratinization and marked nuclear atypia of superficial cells (Fig. 19-24A). **The desquamated squamous epithelial cells are of variable, abnormal shapes with abundant deeply**

eosinophilic cytoplasm and enlarged, hyperchromatic nuclei, usually accompanied by keratinized squamous cells with pyknotic or karyorrhectic nuclei. The presence of these latter cells in a tracheobronchial specimen postlaryngectomy indicates cautious interpretation. Even so, cytologic abnormalities as have been extensively studied and described by Nunez et al (1966) may be indistinguishable from squamous carcinoma (Fig. 19-24B,C) and can lead to an erroneous diagnosis. It is essential to have the history of tracheostomy and to be aware that the epithelial abnormality is in the trachea, whereas squamous lung cancer arises more distally in lobar or segmental bronchi. If in doubt, additional specimens should be obtained from lobar bronchi, which will yield only benign bronchial epithelium in patients with tracheitis sicca.

Figure 19-24 Tracheitis sicca. *A.* There is marked nuclear hyperchromasia in superficial cells of the dry, metaplastic tracheal epithelium. *B,C.* Tracheal aspirate cytology smear and cell block section from another patient with postlaryngectomy tracheitis sicca showing metaplastic squamous cells mimicking squamous carcinoma. (*B*: High magnification.)

“Repair”

In 1988, Rosenthal introduced the term *repair* to describe cytologic abnormalities in the bronchial tree that were reminiscent of those occurring in the uterine cervix (see Chap. 10). The principal feature of these abnormalities is the presence of prominent nucleoli in otherwise unremarkable bronchial epithelial cells (see Fig. 19-19D). To our knowledge, there is no diagnostic significance to this finding, so long as the bronchial epithelial cells retain intact structure. Enlarged nucleoli may also occur in metaplastic cells of **patients who have had prolonged tracheal intubation**. Such cells, usually observed in tracheal aspirates, have been described and illustrated in Chapter 21.

Prominent nucleoli may also be observed in bronchial cells from patients with **respiratory distress syndrome**, including infants receiving oxygen therapy (discussed in the closing pages of this chapter), in burn patients (Cooney et al, 1972), and after radiotherapy (see below). Pneumocytes type II with prominent nucleoli are also seen in atypical pneumonias (see discussion below and Figs. 19-27 and 19-28).

Benign Abnormalities of the Squamous Epithelium

Inflammatory Changes

Inflammatory changes within the **squamous mucosa of the upper respiratory tract** are of some importance in cytologic

P.596

interpretation since they can produce cellular abnormalities that may be confused with squamous cancer. In acute inflammatory processes involving the oral or oropharyngeal mucosa, there may be **necrosis of squamous cells**, manifested by nuclear pyknosis and apoptosis (karyorrhexis) with frayed cytoplasm. If there is **ulceration or erosions**, numerous **small squamous cells** originating from the deeper layers of the squamous epithelium make their appearance singly or in clusters (see Fig. 19-7B). The **nuclei** of such cells often have **coarse chromatin** and a **heavy nuclear membrane**. Any confusion with squamous cancer should be readily ruled out by the uniform appearance of these cells, their smooth nuclear configuration, and presentation in coherent cell clusters. These changes are also discussed in Chapter 21. Significant abnormalities of squamous cells may occur as a consequence of **radiotherapy** (see below).

“Pap” Cells

In sputum of patients with an **upper respiratory tract infection and laryngitis**, especially during cold weather, **small squamous cells with dark, round or oval, single nuclei** may be seen. (Fig. 19-25A). They have been named **Pap cells**. Dr. Papanicolaou is alleged to have observed these cells in his own sputum, examined because of a cough, and was concerned about their appearance. Indeed, superficial observation may give rise to some concern because of the nuclear hyperchromasia. However, the small size and regular nuclear outline of these generally uniform squamous cells should readily identify them. Histologic section of inflamed laryngeal mucosa in at least some cases demonstrates reactive epithelium that appears to be the source of these cells (Fig. 19-25B). “Pap cells” are not a specific indicator of laryngitis and are probably derived from other sites of regenerative epithelium in the respiratory tract as well.

Abnormalities of Alveolar Lining Cells

Bronchial “Metaplasia” of Alveolar Epithelium

In a variety of chronic fibrosing and obstructive processes, **the pulmonary alveoli are lined by one or more layers of small cuboidal or columnar epithelial cells that are in continuity with and identical or similar to the adjoining bronchioles** (Fig. 19-26). This process is observed in **chronic pneumonias of varying etiology**, in **pulmonary fibrosis**, in **areas adjacent to scars** or old infarcts, and in some disorders associated with cystic degeneration of the lungs, the **so-called honeycomb lung** (Meyer and Liebow, 1965). It is generally accepted that in most cases this is not true metaplasia of alveolar epithelium, but results from an extension of the distal bronchial epithelium.

Figure 19-25 Pap cells. *A.* Small squamous cells found in sputum of some patients with laryngitis, thought to be shed from regenerating epithelium of the larynx. *B.* Histologic section of larynx showing hyperplasia of immature regenerating laryngeal epithelium in a patient with prolonged severe laryngitis.

Figure 19-26 Bronchial metaplasia of alveoli. Histologic section of “honeycomb lung” in which alveolar epithelium is replaced by cuboidal or columnar bronchial epithelium.

Cytology

It may be possible to recognize bronchial metaplasia of air spaces in honeycomb lung by the presence of cuboidal or columnar epithelial cells accompanying the alveolar macrophages in a carefully performed BAL specimen. Such a specimen ordinarily contains few or no bronchial epithelial cells, and their presence would suggest alveolar bronchial metaplasia.

Abnormalities of Pneumocytes Type II

Pneumocytes type II are **highly reactive cells that respond to various pathologic processes by morphologic changes**

P.597

that may perfectly mimic adenocarcinoma or its precursor lesions in cytologic samples.

Histology

In a great variety of pathologic conditions, the **pulmonary alveoli are lined by or contain large and prominent alveolar epithelial cells** (Fig. 19-27A). These cells are **pneumocytes type II**, as evidenced by **positive immunoreaction with antisurfactant antibody** (Fig. 19-27B), **positive cytokeratin expression**, and by **electron microscopy** (see Fig. 19-4C,D). The cells are **large, cuboidal or rounded, with large, vesicular or hyperchromatic nuclei and readily visible, often prominent nucleoli**. While this is a benign reactive process, it may closely mimic atypical alveolar hyperplasia, a putative precursor of adenocarcinoma (Nakayama et al, 1990) (see Chap. 20). The spectrum of pulmonary diseases with reactive hyperplasia of

pneumocytes type II is vast and includes **viral pneumonitis, chronic pneumonias, pulmonary fibrosis of various etiologies, fibrosing alveolitis, infarcts, and effects of radio- and chemotherapy**. Pneumocytes type II may form small tumor nodules in **tuberos sclerosis** (Myers, 1999).

Cytology

In past studies of cytologic material from the respiratory tract, reactive hyperplastic pneumocytes were usually identified descriptively as atypical or abnormal “bronchoalveolar cells.” Their identity as pneumocytes type II is relatively recent (Grotte, 1990). Although their benign nature is usually evident in histologic sections, when seen **in cytologic preparations, atypical pneumocytes type II are a potentially important source of false-positive diagnoses of adenocarcinoma** (Nakanishi, 1990; Nakayama et al, 1990; Kerr et al, 1994; Kitamura et al, 1999). They may be seen in sputum, bronchial aspirates, BAL or FNA specimens from patients with persisting pneumonic infiltrates. These pneumocytes appear singly, in flat plaques, or in rosette-like groups of epithelial cells about the size of parabasal cells (Fig. 19-28A-C). They have finely textured cyanophilic cytoplasm and frequently fine or sometimes large cytoplasmic vacuoles (Fig. 19-28D). **Nuclei are large and may be smoothly configured with finely textured chromatin, or irregular with moderately coarse chromatin and single or multiple nucleoli**. In some cases, it may be difficult or impossible to differentiate from atypical alveolar hyperplasia or even adenocarcinoma.

Figure 19-27 Hyperplasia of pneumocytes, type II. *A.* Histologic section of lung showing thickened alveolar septa surfaced by hyperplastic alveolar epithelium in a case of interstitial pneumonia. The cells are clearly different from bronchial epithelium and consistent with hyperplasia of type II pneumocytes. *B.* Same specimen of lung as in (*A*) above. The hyperplastic alveolar epithelial cells react with an antibody to surfactant in an immunoperoxidase reaction, confirming their identity as pneumocytes type II. (*B*, courtesy of Dr. Allen Gown, Seattle, Washington.)

The cells illustrated in Figure 19-28D were transiently present in the sputum of a patient following pulmonary infarction and raised suspicion of adenocarcinoma, but were ultimately interpreted as atypical type II pneumocytes. Scoggins et al (1977) described three patients with pulmonary infarction and false cytologic diagnoses of adenocarcinoma. Bewtra et al (1983) reported nine cases in which the most severe cytologic abnormalities were in the second and third week postinfarction. Johnston (1992) also stressed the misleading nature of cytologic atypias associated with pulmonary infarct. We have observed similar, marked cytologic abnormalities associated with pulmonary infarct, but their transient nature is an important diagnostic clue.

Viral pneumonias are another, more common source of reactive, hyperplastic pneumocytes. Figure 19-29A-C demonstrates cells observed in the sputum of a 60-year-old woman with a febrile illness diagnosed as viral pneumonia. Lung biopsies carried out because of suspected adenocarcinoma demonstrated interstitial fibrosis of usual interstitial pneumonia with obsolete alveoli lined by large cuboidal cells with large nuclei and nucleoli. Immunostaining by Dr. Allen Gown confirmed that alveolar lining cells bound pancytokeratin and surfactant (AT10) antibodies, confirming their identity as pneumocytes type II (Fig. 19-29D; see also Figs. 19-4C, 19-27B). The cells disappeared from her sputum 2 weeks later, and the patient has remained well for 10 years following this episode.

In a study of BAL cytology specimens from a series of 38 patients with **acute respiratory distress syndrome**,

P.598

Stanley et al (1992) noted that **type II pneumocytes were transiently present during the early and organizing (reparative) stages of the disease** but did not persist after day 32 following onset of illness. Chemotherapy for cancer also induces atypias that may mimic cancer, and in some cases probably represents drug-induced carcinogenesis. This is discussed in the closing pages of this chapter.

Figure 19-28 Hyperplasia of pneumocytes type II. *A.* FNA cytology specimen from the case illustrated in Figure 19-27. Flat plaques of cuboidal and rounded type II alveolar pneumocytes are seen among larger pulmonary macrophages (Diff-Quik). *B.* Alveolar pneumocytes in a bronchial lavage specimen of another patient. The cells are rounded with relatively large nuclei, delicate chromatin and prominent nucleoli. *C.* Rosette-like cluster of alveolar pneumocytes with hyperchromatic nuclei mimicking adenocarcinoma. *D.* Large, vacuolated cells with enlarged nuclei, coarse chromatin and prominent nucleoli. These cells mimicking adenocarcinoma were present transiently after pulmonary infarction and interpreted as reactive pneumocytes (Case courtesy of Dr. Eileen King, San Francisco, California).

The important point is that **utmost caution is warranted in the interpretation of cytologic abnormalities from patients with known febrile illness, chronic lung disorder, unexplained diffuse opacity of the lung, and in patients receiving anticancer chemotherapy or radiotherapy.** Accurate and complete clinical information is essential to

avoid diagnostic pitfalls.

Abnormalities of Pulmonary Macrophages (Dust Cells)

Alveolar macrophages may display morphologic abnormalities that require careful interpretation.

Nuclear Abnormalities

Multinucleation

Bi-, tri-, and multinucleated histiocytes or macrophages are often seen in sputum in the absence of any significant inflammatory process. Large giant cells with numerous peripheral nuclei, resembling the Langhans' cells of tuberculosis, may occur in nonspecific inflammatory processes (see below). Thus the **mere presence of multinucleated macrophages in cytologic material cannot be correlated with a specific disease state.**

Prominent Nucleoli

Prominent nucleoli are occasionally observed in macrophages. The concomitant presence of dust granules within the cytoplasm is helpful in identifying the cells correctly. This finding is of no diagnostic significance.

Degenerative Nuclear Changes

Degenerative nuclear changes that may be confused with cancer are rarely observed in alveolar macrophages. The **cells are typically large** and are provided with **correspondingly large, hyperchromatic, but homogeneous nuclei** that are

P.599

sometimes irregular and multiple. These cells are described and illustrated in Chapter 21.

Figure 19-29 Atypical pneumocytes type II in viral pneumonia. A-C. Small clusters and single cells with large, hyperchromatic nuclei, some with visible nucleoli, in sputum of a 60-year-old woman with viral pneumonia. D. Lung biopsy revealed interstitial fibrosis consistent with usual interstitial pneumonia. The markedly prominent alveolar lining cells (pneumocytes) bind the anti-surfactant antibody A10 (D, courtesy of Dr. Allen Gown, PhenoPath Laboratories, Seattle, WA).

Lipid Pneumonia

Lipid pneumonia may be exogenous or endogenous.

Exogenous Lipid Pneumonia

This disorder results from **aspiration of an oily substance into the lung**. Thus, habitual users of mineral oil or oily nose drops are subject to the disease. The **radiologic appearance** of exogenous lipid pneumonia is that of a localized **infiltrate or mass mimicking lung cancer**, usually in the lower lobes. Although this disorder is much less common today than a generation ago, it is still encountered from time to time, particularly among older persons, and differentiation from lung cancer is of paramount clinical importance.

Because oil aspirated into the lung cannot be absorbed or metabolized, it is **phagocytized by pulmonary macrophages** that carry some of the oil droplets to regional lymph nodes. However, much of the oil remains within the lung where the oil-containing macrophages generate a **granulomatous inflammatory reaction** in the pulmonary parenchyma. This so-called **golden pneumonia** gets its name from the gross appearance of the lipid-rich pneumonic tissues.

Cytology

Sputum is an excellent medium for diagnosis of lipid pneumonia. A deep cough specimen contains lipid-filled macrophages that are diagnostic of this disease. **The characteristic finding of large macrophages with large cytoplasmic vacuoles or abundant bubbly or lacy, vacuolated cytoplasm, representing lipid-filled vacuoles, is pathognomonic of this disease** (Fig. 19-30A). The **nuclei are single or multiple, but small and unremarkable** in appearance. The **differential diagnosis** is limited to **mucus-producing cancer cells**, which, as a rule, have less cytoplasm and display highly **abnormal nuclei**. Also, the cytoplasmic mucin in cancer cells is almost invariably limited to a single vacuole, unlike the bubbly, multiple vacuoles in the cytoplasm of lipid histiocytes. If in doubt, a fresh specimen of sputum can be stained for fat with Oil-red-O (Fig. 19-30B) or Sudan black.

Pulmonary macrophages in the presence of mucus-producing lung cancer may contain phagocytized mucin, but again, as a usually single, fairly large vacuole. Rarely will there be confusion with the cells of lipid pneumonia, and in those unusual cases, the issue can be settled by **staining for mucin** to determine the nature of the cytoplasmic droplets.

P.600

Figure 19-30 Lipid pneumonia. A. A large multinucleated macrophage with phagocytized lipid (lipophage) in sputum of a patient with lipid pneumonia. The **multiple cytoplasmic vacuoles or abundant lacy cytoplasm of mono- or multinucleated macrophages are pathognomonic**. B. Oil-red-O stain for lipid in an unfixed, air-dried specimen. C. Endogenous lipid pneumonia due to tissue destruction in association with organizing pneumonia. These lipid-filled histiocytes have very fine vacuoles, are usually mononuclear and not enlarged. D. Lipid histiocytes of endogenous lipid pneumonia in an FNA sample stained with Diff-Quik.

Endogenous Lipid Pneumonia

Endogenous lipid pneumonia is a complication of pulmonary disease in which there is tissue destruction and release of tissue lipids that are phagocytized by macrophages.

The lipid-filled macrophages accumulate at these sites of tissue damage. This may involve lung parenchyma distal to an obstructing bronchial lesion such as **carcinoma**, or in association with **organizing pneumonia, necrotizing granulomatous inflammation**, or other chronic inflammatory and destructive processes including the effects of **radiotherapy**. Endogenous lipid pneumonia is more common today than exogenous lipid pneumonia. The **radiologic presentation is typically that of the primary lung disease, and endogenous lipid pneumonia is usually an incidental finding**.

Cytology

Macrophages with large, bubbly vacuoles, so characteristic of exogenous lipid pneumonia in sputum, are rarely observed in endogenous lipid pneumonia. **Small, finely vacuolated macrophages** are more characteristic (Fig. 19-30C,D), but they are seldom recognized in sputum and are not specific since they can also be found in sputum of smokers (Roque and Pickren, 1968). The cytologic diagnosis of endogenous lipid pneumonia **is virtually always made by aspiration biopsy (FNA), obtained because of clinical suspicion of bronchogenic carcinoma**. The **characteristic lipid-filled macrophages** may be accompanied by cancer cells. In cases in which such macrophages are observed, the nature of the principal lesion must be urgently clarified by additional cytologic or histologic samples.

The differential diagnosis is primarily with mucinous adenocarcinoma, as discussed above. Among the **few other conditions that mimic endogenous lipid pneumonia** are **Gaucher's disease** involving the lungs, and side effects of **Amiodarone**, a cardiac anti-arrhythmic drug that is associated with interstitial fibrosis and foamy macrophages in the lung. Both entities are described below.

Heart Failure Cells (Hemosiderin-Laden Macrophages, Siderocytes)

"Heart failure cells," so named because they may be found in sputum or BAL specimens of patients with chronic congestive heart failure, are **pulmonary macrophages containing a large amount of phagocytized hemosiderin**, which sometimes obscures the nuclei of the macrophages.

P.601

The **hemosiderin**, a product of hemoglobin break-down, is a **golden-brown, iron-containing crystalline pigment** (Fig. 19-31A). Such cells are the sequelae of bleeding into the pulmonary parenchyma. In **heart failure**, bleeding into the air spaces of the lung is usually caused by microscopic oozing from congested alveolar septal capillaries. The hemoglobin breakdown products are phagocytized by macrophages. It should be emphasized that "heart failure cells" are not a specific indicator of heart disease, but may be seen, for example, **after pulmonary**

infarction or bleeding of any cause into the lung. Friedman-Mor et al (1976) observed hemosiderin-laden macrophages (siderocytes) in specimens from patients in **shock**, and Naylor found them in patients with **Goodpasture's syndrome** (personal communication), a disease in which vascular damage results from autoantibodies to the basement membrane. In the very rare cases of **primary pulmonary hemosiderosis**, the sputum also can be expected to have an abundance of hemosiderin-containing macrophages.

Figure 19-31 “Heart failure” cells. *A.* Hemosiderin blood pigment in the cytoplasm of macrophages has a characteristic crystalline brown or golden appearance. Hemosiderin may be so abundant in some histiocytes as to obscure the nucleus. *B.* If in doubt, hemosiderin can be identified by a deep blue color in the Prussian blue, ferroferricyanide stain for iron.

Granules of hemosiderin should not be confused with other pigments that may be phagocytized by macrophages. **Common dust particles** are usually black and coarse, or so fine as to alter the coloration of the cytoplasm without visible particulates. **Brown melanin pigment** lacks the crystalline appearance of hemosiderin. The rare occurrence of **bile** in severely jaundiced patients, or in the cytoplasm of metastatic hepatocellular carcinoma, is a vaguely greenish, granular, but not crystalline pigment. If in doubt, **hemosiderin pigment can be easily identified by the characteristic blue color of iron in the Prussian blue ferroferricyanide staining reaction** (Fig. 19-31B).

CYTOLOGY OF INFLAMMATORY PROCESSES

Acute Bacterial Inflammation

Cytology

Acute bacterial inflammatory processes include **pneumonias** of various etiologies, lung **abscess** and **purulent bronchitis**, and result in tissue breakdown. In these diseases, the **sputum** and **aspirated bronchial material** are partly or wholly made up of **purulent exudate**, a mixture of necrotic cellular material and intact and damaged polymorphonuclear leukocytes (see Fig. 19-11A). The Papanicolaou-stained smears appear predominantly **basophilic** (cyanophilic) because of the abundance of necrotic nuclear material forming **threads and amorphous masses of DNA** that stain blue with hematoxylin. Although one is often tempted to consider such smears to be of limited diagnostic value, careful study may reveal underlying (or complicating) causes of the inflammatory process, including various bacterial, fungal, viral, or parasitic infections. The identification of causative organisms is of special importance for effective treatment of patients with AIDS. Also, **because lung cancer, particularly squamous carcinomas, may occasionally be masked by coexisting inflammation, careful**

screening for cancer cells is mandatory.

Identification of Specific Bacterial Organisms

The great majority of acute inflammatory processes in the lung are caused by bacteria, most commonly ***pneumococci***, ***streptococci***, ***staphylococci***, and ***Klebsiella* species**. Even with special bacteriologic stains, there are few morphologic features that allow more than a presumptive identification of the bacterial agent or agents in cytologic preparations. Staphylococci, streptococci, and pneumococci may sometimes be tentatively identified by their configuration and growth patterns in chains (streptococci) or clusters (staphylococci). Gram-negative intracellular micrococci are typical of *Neisseria* species. The gram-positive organisms stain blue with hematoxylin. ***Legionella micdadei***, a cause of Legionnaire's disease, was identified in bronchial washings and pleural fluid by Walker et al (1983) as either extracellular or intracellular small, delicate, gram-negative and acid-fast positive bacilli within the cytoplasm of neutrophils and macrophages. In most cases, bacteriologic culture is required for confirmation and specific classification of the causative organisms and to determine their antibiotic sensitivities. A growing list of **nucleic acid probes and monoclonal antibodies** provide new

P.602

bacteriologic techniques to accelerate and enhance diagnostic results. Other less common agents that may occasionally cause acute inflammation are discussed below.

Atypical Pneumonias

Atypical pneumonias in adults are caused by ***mycoplasma***, by **viruses** including adenovirus, rhinovirus and influenza virus, by **some fungi** including ***Pneumocystis carinii*** and occasionally bacterial agents. In children and some adults, **respiratory syncytial virus** may be at fault (see below for discussion of fungal and viral manifestations in cytologic material).

The patients usually have symptoms of an **acute febrile respiratory illness with a poorly defined segmental infiltrate on x-ray**. In most cases, the disease is transient, lasting from a few days to a few weeks, and ends by resolution of the pulmonary infiltrate. In some patients, however, the disease may become chronic with progressive interstitial fibrosis.

Cytology

During the **acute and subacute stages** of atypical pneumonias, cytologic samples of **sputum** may pose **significant problems in differential diagnosis**. Following a vigorous bout of coughing, there is often abundant desquamation of **ciliated bronchial cells**, some showing nonspecific atypias in the form of **cellular and nuclear enlargement and enlarged nucleoli**. Other nonspecific abnormalities may include occasional **papillary clusters of hyperplastic bronchial cells** (Creola bodies) and **ciliocytophthoria** (see above), which can occur in any viral infection (Pierce and Hirsch, 1958), but is particularly likely in adenovirus pneumonia (Pierce and Knox, 1960). An extraordinary exfoliation of papillary groups of bronchial epithelium (Creola bodies) seen in the bronchial aspirate from a 1-year-old child with viral pneumonia is illustrated in Figure 19-32A-C.

Figure 19-32 Bronchial cell atypia in viral pneumonia. A-C. Numerous groups of hyperplastic bronchial epithelial cells (Creola bodies) with hyperchromatic nuclei in the bronchial aspirate of a 1-year-old boy with atypical (viral) pneumonia. Note the persistence of cilia in some of the cells. (Case courtesy of Dr. Goodman.) (B,C: oil immersion.)

Abnormalities of type II pneumocytes, previously discussed and illustrated in Figure 19-29, are another consequence of the pneumonic process.

Knowledge of the clinical setting is always important, but particularly in these difficult cases. Significant epithelial abnormalities in the smaller bronchioles and adjacent alveolar lining cells were noted in autopsy studies of viral pneumonias as long ago as the influenza pandemic of 1918 (Winternitz, 1920). **Thus, the history of an acute, febrile illness should act as a deterrent to the cytologic diagnosis of cancer.** The patient should be monitored with additional specimens until symptoms abate and radiologic abnormalities resolve, or until there is confirmed evidence of cancer on repeat specimens. The cytologic changes accompanying viral pneumonia can be expected to clear over a period of 4 to 6 weeks, and often sooner.

Chronic Inflammatory Processes

Chronic Bronchitis and Pneumonia

These disorders are usually the sequelae of acute bacterial infections or atypical pneumonias and are recognized clinically

P.603

because of persisting cough, low-grade fever, and various roentgenologic images. The cytologic manifestations of chronic bronchitis and pneumonia in sputum and bronchial washings encompass a range of benign abnormalities. **Nonspecific atypias of bronchial lining cells** and **squamous metaplasia** are the most typical reactions to chronic inflammatory processes. **Reserve cell (basal cell) hyperplasia** and an **increase in mucin-secreting cells** are common.

Chodosh (1970), who followed patients with chronic bronchitis by total and differential cell counts of 24-hour sputum samples, observed that the total number of exfoliated epithelial cells rose and fell according to the stage and activity of their disease, yet the differential count of various epithelial cell types (e.g., ciliated, nonciliated, goblet cells) remained relatively constant.

As expected, there was an increase in neutrophils and a drop in macrophages during acute exacerbations of disease, whereas the reverse sequence occurred during recovery.

Diffuse Alveolar Damage

Diffuse alveolar damage is the result of injury to distal alveoli resulting from a single injurious event, usually within the prior few days to weeks. The damage may be extensive, or it may be limited to a small region of the lung. There are a great variety of causes including inhalants, drugs, oxygen toxicity, irradiation, shock, and sepsis. Histologically, there is an early, acute phase characterized by pulmonary edema, a proteinaceous exudate, and **hyaline membrane formation**. This is followed in a few days or a week by hyperplasia of type II pneumocytes in what is apparently a reparative effort. The damage may resolve or may be followed by organization and fibrosis.

Cytologic samples obtained by BAL early in the course of the disease consist of amorphous proteinaceous material, alveolar macrophages, neutrophils, and atypical type II pneumocytes, described above (Beskow et al, 2000).

Interstitial Lung Diseases

Under this heading, there are a number of clinically divergent lung disorders grouped as **idiopathic interstitial pneumonias**. They have **common cytologic denominators** and cannot be specifically identified on the basis of cytologic findings, although various special techniques have been applied to specimens of BAL in an attempt to clarify the nature of some abnormalities. In this group of diseases, it is essential to have accurate knowledge of clinical history and roentgenologic findings to avoid errors of interpretation.

Idiopathic Interstitial Pneumonias

Pathology and Clinical Data

The interstitial pneumonias were first defined by Liebow (1975) and recently reclassified by Katzenstein (1997). Idiopathic interstitial pneumonias comprise a heterogeneous group of disorders of unknown etiology (hence "idiopathic"), having in common **inflammation and progressive fibrosis of alveolar spaces, resulting in obliteration of alveoli and synchronous dilatation of bronchioles**, leading to formation of pseudoglandular spaces. Noguee et al (2001) described a mutated gene regulating the production of surfactant protein C in a case of familial interstitial disease in an adolescent girl. There is no evidence, so far, that this or similar mechanisms are operative in other sporadic cases. The final stage of the disease is the so-called **honeycomb lung (or end-stage lung)** characterized by grossly visible cysts surrounded by firm, fibrosed lung tissue. **Early histologic changes include hypertrophy of alveolar pneumocytes type II, gradually replacing alveolar epithelium by cuboidal cells with large nuclei, and hypertrophy of bronchiolar epithelium with bronchiolar metaplasia in alveoli.**

The common clinical denominator of these disorders is **progressive difficulty in breathing (dyspnea)** caused by the impaired exchange of oxygen and carbon dioxide across the alveolar septum (alveolar-capillary block). Roentgenologic studies show a diffuse and progressive opacification of both lung fields.

Although from a cytologic point of view, this entire group of diseases can be considered as a single entity, there are subtle clinical and histologic differences among the various entities, which have been subclassified as follows:

- Usual interstitial pneumonia (UIP)

- Nonspecific interstitial pneumonia (NSIP)
- Desquamative interstitial pneumonia (DIP)
- Acute interstitial pneumonia (AIP) or Hamman-Rich syndrome
- Respiratory bronchiolitis-interstitial lung disease (RB-ILD)
- Chronic "idiopathic" pulmonary fibrosis

In addition, several diseases of known or suspected cause may result in a similar clinical and pathologic picture and may be considered in this group of disorders. These are:

- **Farmer's lung** and various other types of **allergic pneumonitis (eosinophilic pneumonia)**
- **Pneumoconioses** (e.g., silicosis, asbestosis, anthracosis)
- **Sarcoidosis** (see below)
- **Drug-induced pneumonitis** (to be discussed separately later in this chapter)

Cytology

While the diagnosis often is apparent from clinical and radiologic findings, there may sometimes be **striking atypias of reactive bronchiolar epithelium or pneumocytes type II that can raise questions of adenocarcinoma**. These were discussed above.

Localized chronic interstitial inflammatory processes that mimic lung cancer are most likely to be investigated by FNA biopsy. In most cases, the aspirate is easily recognized as inflammatory and benign, but on occasion, there is **exuberant reactive hypertrophy and hyperplasia of bronchoalveolar epithelium derived from pseudoglandular spaces in the lung, lined by atypical cuboidal cells**. The aspirate may then yield **globoid or ovoid papillary clusters** of cuboidal bronchiolar or alveolar lining cells with

P.604

small but visible nucleoli, usually arranged in a monolayer (Figs. 19-27 and 19-28). The small size of these cells, their uniform appearance, and regular small nuclei should help prevent a mistaken diagnosis of adenocarcinoma. Kern (1965) reported significant cell abnormalities in sputum of 11 patients with interstitial pneumonia, some with the **Hamman-Rich syndrome**. In two patients, the atypical cells led to an erroneous diagnosis of adenocarcinoma. In retrospect, Kern was dealing with atypical pneumocytes, type II.

Another important source of diagnostic error in aspiration biopsy of the lung, particularly in chronic inflammatory disease, is the presence of mesothelial cells, discussed in Chapters 20 and 26.

With the introduction of **BAL**, many attempts have been made to identify these inflammatory disease processes more specifically by differential cell counts and immunophenotyping the cells, and by chemical analysis of the supernatant. The fundamental cytologic observations are as follows: **In normal, nonsmoking persons, the total cell count in BAL specimens is lower than in smokers**; the difference is caused by an **increase in alveolar macrophages in smokers**. In various **interstitial lung diseases, there is an increase in macrophages, lymphocytes, and polymorphonuclear leukocytes**. A chronic process is favored when lymphocytes are predominant, and a more acute inflammatory pneumonitis is favored when polymorphonuclear leukocytes are increased. Further characterization of macrophages and lymphocyte subtypes has been possible for some time through immunophenotyping (Costabel et al, 1985), but is of little practical value at present, except perhaps in suspected lymphoproliferative disorders.

Figure 19-33 Tuberculosis. *A* Slender, elongated epithelioid cells with elongated, sometimes carrot-shaped nuclei and *(B)* multinucleated Langhans' giant cell in the sputum of a patient with tuberculosis. (Case courtesy of the late Dr. Magnus Nasiell, Stockholm.) *C*. Multinucleated Langhans'-like cell in sputum of a patient with viral pneumonia. The finding of such a cell per se is nonspecific. *D*. FNA of tuberculosis in lung showing a cluster composed of epithelioid histiocytes and spindle cells suggestive of a granuloma.

BAL has also been studied in **adult respiratory distress syndrome** (summary in Hyers and Fowler, 1986). This potentially lethal, but occasionally reversible disorder is a complication of prolonged exposure to high concentrations of oxygen. It is characterized by the presence of **polymorphonuclear leukocytes and high-molecular-weight plasma proteins** in the lavage specimen, reflecting the increased permeability of damaged alveolar capillaries and interstitial tissues in the alveolar septa.

Giant-Cell Interstitial Pneumonia

Hard-metal workers who are exposed to the dust of a number of metallic industrial pollutants such as tungsten, cobalt, diamond dust, titanium, beryllium, and others may develop a peculiar form of chronic interstitial lung disease characterized by the presence of **large multinucleated giant cells**

P.605

and fibrosis of interalveolar septa. There are several reports of cytologic abnormalities in this disease (Valicenti et al, 1979; Davison et al, 1983; Tabatowski et al, 1988). The **sputum, bronchial washings, and BAL** fluid in such patients are reportedly characterized by the presence of **numerous giant cells with multiple nuclei**. Particles of phagocytosed material may be observed in the cytoplasm, and the metals can be characterized by analytical electron microscopy. Kinoshita et al (1999) reported two well-documented cases due to tungsten carbide and cobalt in which **bizarre macrophages** were found in BAL specimens. It now appears that the likelihood of disease, at least in the case of exposure to **beryllium**, is greatly increased in individuals with a genetic predisposition to develop sensitivity to this metal (Marshall, 1999). Tabatowski et al emphasized that the cytologic diagnosis of interstitial pneumonia must be supported by clinical and occupational data. The **presence of giant cells in cytologic samples is not specific**, per se, as such cells may occur in a broad variety of chronic inflammatory disorders, and sometimes without an obvious cause.

Giant-cell pneumonia of newborn infants and children is idiopathic or ascribed to a virus, most commonly to measles.

Aspiration Pneumonia

Individuals who have a suppressed cough reflex, for example, as the result of a stroke, alcohol or drug intoxication or postanesthesia, are at risk of aspiration pneumonia (Marik, 2001). Aspiration pneumonia may be acute or chronic. In **acute aspiration pneumonia**, foreign material inspired and then expelled in a sputum sample cannot be distinguished from contaminants of the oral cavity; the cytologic findings are nonspecific and reflect the degree of associated acute inflammation. **A finding of foreign material in bronchial aspirate or lavage specimens** excludes the possibility of oral cavity contamination and is **diagnostic of aspiration**.

In cases of **chronic aspiration pneumonia**, one may find foreign material within the inflammatory exudate in a cough specimen, either partially embraced by macrophages or phagocytized by foreign body giant cells. The exudate is pleomorphic, and includes many polymorphonuclear leukocytes as well as the lymphocytes and histiocytes that typically characterize chronic inflammation. The diagnosis of aspiration pneumonia, whether acute or chronic, may have important legal implications.

Quantitation of lipid-laden macrophages has been proposed as an index of aspiration pneumonitis (Corwin and Irwin, 1985) and applied to BAL in adult patients (Silverman et al, 1989; Langston and Pappin, 1996; Knauer-Fischer and Ratjen, 1999) and to various cytologic samples from infants and children (Colombo and Hallberg, 1987; Collins et al, 1995; Yang et al, 2001). The lipid-laden macrophages can be visualized in air-dried, unfixed smears by staining with the oil-soluble dye, Oil-red-O (see Fig. 19-30B), or after fixing in formalin or formalin vapor (Yang et al, 2001). We found that the stain can work adequately on conventionally prepared smears of bronchial irrigation or sputum specimens preserved in 50% alcohol but not processed through xylol or other lipid solvents. The proportion of lipid-laden cells versus the total number of macrophages was proposed as a grade of risk by Corwin and Irwin (1985). The grading system later was simplified by Yang et al (2001) who concluded that an absolute or relative increase of lipid-laden macrophages was a sensitive but not particularly specific method for the diagnosis of aspiration pneumonitis in pediatric patients.

Specific Inflammatory Processes

Tuberculosis

Clinical Data

Tuberculosis, caused by the **acid-fast *mycobacterium tuberculosis***, is a worldwide infectious disease still rampant in the developing countries. It has seen a recent resurgence in the US and other industrialized countries because of AIDS. The disease has two principal forms depending on the portal of entry of the highly infectious organisms. The common **pulmonary form** is caused by inhalation, whereas the rare **intestinal form** is caused by ingestion, usually in milk.

The disease is characterized by formation of minute granules (granulomas), composed of immobilized macrophages that resemble epithelial cells and are therefore called **epithelioid cells**. Fusion of the epithelioid cells leads to the formation of giant cells with a peripheral wreath of nuclei known as **Langhans' cells**. The center of these granulomas often is necrotic and the cheese-like necrotic tissue is known as **caseous necrosis**.

In pulmonary tuberculosis, the upper lobes are first involved, and as the disease progresses,

large areas of confluent granulomas undergo caseous necrosis. Expulsion of the necrotic material through the bronchi leads to formation of **cavities** that are the hallmark of late stages of the disease. The sputum of patients with cavitating tuberculosis is rich in acid-fast bacteria and is the most important source of infection to others. Prevention of cavity formation by drugs is the main goal of public health measures.

Early diagnosis followed by treatment is curative of pulmonary tuberculosis. The customary mode of disease detection is by culture of the organism or by a specific polymerase chain reaction (PCR) (see Chap. 3). Still, there are many cases of the disease that are not recognized clinically and may be mistaken for other infectious or neoplastic diseases. Recognizing the possibility of tuberculosis in cytologic samples would be of paramount importance to the patient and to society.

Cytology

Nasiell et al (1972) were among the first to study the sputum and bronchial secretions of a large group of patients with pulmonary tuberculosis. They reported identifying the component cells of the tubercle, the **epithelioid cells**, and **Langhans' giant cells**, in sputum (Fig. 19-33A,B). The identifiable **epithelioid cells** usually appeared in loose clusters as **elongated or somewhat spindly slender cells, sometimes carrot-shaped with one end broader than the**

P.606

other, and were a bit smaller than bronchial cells. They had eosinophilic cytoplasm with poorly defined cell borders, and pale nuclei that generally followed the elongated shape of the cells. It is likely that epithelioid cells with a more rounded configuration were present as well, but could not be distinguished from other mononuclear macrophages. The **multinucleated Langhans' giant cells** have **peripherally arranged nuclei, but multinucleated giant cells with centrally placed nuclei also may be present**.

The original study by Nasiell et al was reported to show a high degree of specificity for epithelioid cells and Langhans' giant cells, and the combination of the two was considered most specific. In a later report from the same group, however, their original observations could not be sustained (Roger et al, 1972). **In our own experience, the presence of multinucleated giant macrophages in cytologic material, even giant cells of Langhans' type, is of limited diagnostic value.** Such cells may be observed in a broad variety of other inflammatory disorders (Fig. 19-33C), and in occasional patients for unknown reasons.

Percutaneous FNAs usually yield only granular necrotic debris and a mixture of inflammatory cells, a dirty aspirate, including mono- and multinucleated macrophages with, perhaps, occasional comma-shaped epithelioid cells. The presence of a granuloma-like cluster of spindly (comma-shaped) epithelioid cells and histiocytes in an FNA should raise question of tuberculosis, but is not diagnostic (Fig. 19-33D).

In the BAL specimens of patients with active tuberculosis and sarcoidosis, Hoheisel et al (1994) reported an increased proportion of lymphocytes, predominantly activated T cells. The CD-4/CD-8 ratio of lymphocytes was increased in sarcoidosis (see below) but not in tuberculosis.

The frequently **similar radiologic presentation of tuberculosis and lung cancer, and their occasional coexistence**, must be borne in mind when the cytologic diagnosis of tuberculosis is contemplated. **Confirmation of tuberculosis by bacteriologic studies is essential, particularly in high-risk patients with AIDS** in whom the disease is severe and likely to disseminate. In such patients, the granulomas are less well formed, more often necrotic, and likely to contain a greater number of acid-fast organisms. Unfortunately, stains for acid-fast bacilli in sputum smears or cell block sections have been of very limited value in our hands.

Mycobacterium Avium Intracellulare

Pulmonary infections with the acid-fast bacterium, ***Mycobacterium avium intracellulare*** (MAI), have acquired new significance with the onset of AIDS, and brief discussion of this disease is warranted. Once an extremely rare cause of disease in the human, it is now one of the most common opportunistic infections in AIDS and other immunodeficient patients, in whom it is a potentially lethal infection. The organism is found worldwide in soil and water. Beginning in the lung or gastrointestinal tract, it disseminates throughout the reticuloendothelial system and to the central nervous system. The involved tissues are choked with numerous swollen, foamy macrophages that contain enormous numbers of acid-fast organisms. **Massive abdominal lymphadenopathy and splenomegally caused by an overwhelming MAI infection may mimic a malignant lymphoma.** We are unaware of any systematic cytologic study of pulmonary MAI infection. However, in FNA smears of lymph nodes from those patients, numerous bacterial rods are found within large foamy macrophages. In hematologic stains such as Diff-Quick, the organisms do not stain, but appear as clear or pale oblong structures within the cytoplasm of macrophages (see Chap. 31). In the immunocompetent patient with pre-existing chronic lung disease, MAI can sometimes cause a superimposed indolent granulomatous and cavitating infection that is clinically and pathologically similar to tuberculosis. Indolent infections with *M. avium* have been reported in elderly patients without a known predisposing immunologic defect (Prince et al, 1989).

Other Bacterial Infections

Material for culture can be secured in sputum, BAL, bronchial brush, or FNA specimens. On occasion, unusual bacterial organisms may be identified directly in such specimens. For example, Lachman (1995) identified ***Rhodococcus equi*** in BAL and bronchial brush specimens, and Hsu and Luh (1995) reported ***Fusobacterium nucleatum*** in an FNA.

Sarcoidosis

The granulomatous disease, sarcoidosis, **differs from tuberculosis in that there is no caseous necrosis within the granulomas.** The disease is most common in young African-Americans, and whereas the lung is frequently affected, **sarcoidosis is a systemic disease** of unknown cause. In most patients, the disease is chronic, involving lymphoid tissue and many other organs including the eye, bones, heart, etc.

Mycobacterium tuberculosis has long been suspected of having some role in the pathogenesis of sarcoid, perhaps associated with a defect of cellular immunology. Bacterial proteins of *M. tuberculosis* have been reportedly demonstrated in sarcoid tissue by PCR. Nasiell et al observed both epithelioid cells and multinucleated giant cells in sputum of some of their patients with sarcoidosis.

We have observed well-formed granulomas composed of epithelioid cells and Langhans' giant cells in FNA specimens of several cases of pulmonary sarcoidosis (Fig. 19-34A-C). A characteristic, though not invariable or fully specific feature is the presence of **laminated crystalline inclusions (Schaumann's bodies)** in multinucleated giant cells (Fig. 19-34D). Such cells are suggestive of sarcoidosis.

Zaman et al (1995) reported their findings in **BAL specimens** from a series of 26 patients with sarcoidosis and concluded that in an appropriate clinical setting, **a combination of the following would suggest pulmonary sarcoidosis: multinucleated giant cells** with highly reactive nuclear changes; **reactive alveolar macrophages** and **epithelioid cells**; lymphocytosis; and a clean background. As noted above, Hoheisel et al (1994) found an increased

percentage of lymphocytes in BAL specimens with predominance of activated T cells and an increased CD-4/CD-8 ratio. It should be re-emphasized that the finding of multinucleated giant cells or lymphocytosis in itself is nonspecific, and can be observed in a variety of inflammatory processes or even in the absence of disease.

Figure 19-34 Sarcoidosis. A. Sarcoid granuloma in FNA of lung from a 38-year-old woman and (B) confluent noncaseating granulomas in a needle core biopsy of lung from the same patient. C. Sarcoid granuloma in bronchial cytology of another patient. Note the multinucleated Langhans' giant cell with adherent rounded and elongated epithelioid cells. D. Schaumann body, a laminated crystalline inclusion in a multinucleated Langhans' giant cell, considered very suggestive of sarcoidosis. This was in a sputum specimen from a woman later confirmed to have sarcoidosis on biopsy of a neck node (D, courtesy of Dr. Klaus Schreiber).

If sarcoid is suspected clinically, a transbronchial FNA of mediastinal lymph node may be more effective than percutaneous aspirate (Koerner et al 1975). In those cases, care must be taken not to confuse the epithelioid cells with cancer cells. Even with cytologic or histologic evidence of noncaseating granulomas, however, prudence requires that a final diagnosis of sarcoidosis be confirmed clinically and by negative bacteriologic study.

Actinomycosis and Nocardiosis

Actinomycosis and nocardiosis are suppurative infections caused by **gram-positive branching filamentous bacteria** once thought to be fungi because of their morphology. Both are saprophytic organisms, but may be pathogenic in patients with impaired cellular immunity. Actinomyces grow under conditions of reduced oxygen, and are common inhabitants of the tonsillar crypts and gingival crevices. The organism does not invade healthy tissues and in order to cause disease it must be injected into the tissue under anaerobic conditions, thus usually in association with trauma, for example, in the oral cavity. **Consequently, they may be present in the sputum as contaminants of no clinical importance.** They are **readily identified** by their pattern of growth in colonies **made up of dense masses of hematoxylin-stained, tangled filaments** that radiate outward and tend to be eosinophilic at the periphery (Fig. 19-35A). In the female genital tract, actinomycotic colonies are usually associated with long-term use of an intrauterine device (see Chap. 10). **Pulmonary lesions caused by actinomyces** usually represent secondary or complicating infections of already-damaged or

inflamed lung tissue. Actinomyces derived from tonsillar crypts may produce **lung abscesses** from which the organism can grow into the pleura and chest wall with resulting empyema and fistulous tracts. The actinomycotic colonies are visible grossly as small yellow particles (**sulfur granules**). **If the organism is observed in bronchial brush or bronchial aspirate from an infected segment of lung, or is found in a FNA of a pulmonary lesion, its role as a pathogen is secure** (Koss et al, 1992).

P.608

Figure 19-35 Actinomyces and nocardia. *A.* The long filamentous actinomyces are best visualized at the periphery of the colony and are a common contaminant in specimens of sputum. *B.* Nocardia in sputum, a loose cluster of long, thin, branching filamentous organisms. *C.* Nocardial lung abscess in the same patient.

The clinical presentation of **nocardiosis** is similar to actinomycosis, and usually also is an infection of immunocompromised individuals. It is caused by inhalation of the organism, which is widely present in the soil. **Nocardia is an aerobic branching filamentous bacterium that is grampositive and resembles actinomyces** but is weakly acid-fast. The organism may cause pulmonary abscesses (Fig. 19-35B,C). It does not usually form colonies (“sulfur granules”) characteristic of actinomyces. Culture is required for positive identification of the organism.

Wegener's Granulomatosis

Wegener's granulomatosis is a disease of unknown etiology, characterized by vasculitis of small and medium size vessels and necrotizing granulomatous inflammation involving the upper respiratory tract and lung, where it may sometimes mimic cavitating tuberculosis. Glomerulonephritis and generalized vasculitis are common. In the proper clinical setting, the diagnosis may be suggested by **FNA** of lung that yields **amorphous or filamentous necrotic tissue** (a “dirty” background) and an **inflammatory cellular infiltrate** containing mono- and multinucleated macrophages and, in some cases, epithelioid cells (Fekete et al, 1990; Pitman et al, 1992; Kaneishi et al, 1995). Five cases diagnosed by transbronchial biopsy were reported by Lombard et al (1990). Takeda and Burechailo (1969) observed **smooth muscle cells** in the sputum of a patient with Wegener's granulomatosis, and Hector (1976) described sputum cytology in two cases of Wegener's granulomatosis, but the findings were nonspecific. There is no evidence that sputum is an effective diagnostic technique for this disease.

The diagnosis must be verified by biopsy and by **positive anti-neutrophil cytoplasmic antigen test (cANCA) confirmed by enzyme-linked immunosorbent assay (ELISA) for proteinase 3** (Savige et al, 1999; van der Geld, 2000).

Langerhans' Cell Histiocytosis (Langerhans' Cell Granulomatosis, Eosinophilic Granuloma)

Langerhans' cell histiocytosis in the lung is part of a spectrum of diseases characterized by monoclonal proliferation and infiltration of many organs by Langerhans' cells (Willman et al, 1994; Vassallo et al, 2000). The **Langerhans' cells** are dendritic, antigen-presenting cells, characterized by expression of the CD1a antigen and the presence (in electron micrographs) of penta-layered, rod-shaped intracytoplasmic structures known as **Birbeck granules** (Birbeck et al, 1961).

The Langerhans' cells are associated with eosinophils and, in its localized form, the disorder is called **eosinophilic granuloma**. In cases of multiorgan involvement, the disease was once thought to be a different entity and was called **histiocytosis X** or **Letterer-Siwe disease**. These terms are now obsolete. **The Hand-Schüller-Christian syndrome (a triad of exophthalmos, diabetes insipidus, and bone lesions involving primarily the skull)** is a disease of childhood most often caused by eosinophilic granuloma.

P.609

Langerhans' cell granulomatosis is now thought to represent a reactive rather than a neoplastic process (Lieberman et al, 1996; Vassallo et al, 2000; Yousem, et al, 2001), although clonality has been reported in extrapulmonary lesions (Willman, 1994). It accounts for an estimated 5% of adult patients with interstitial lung disease (Gaensler et al, 1980) who may present with cough and dyspnea. In chest x-rays, the upper and middle lobes of the lung are predominantly involved with interstitial infiltrates, sometimes accompanied by cystic changes. The disease can occur as a single, isolated nodule and mimic carcinoma of the lung (Fichtenbaum, 1990; Khor et al, 2001).

Cytology

When suspected clinically, the diagnosis can be supported by **BAL in which more than 5% of large mononuclear cells are CD1a positive** (Chollet et al, 1984; Auerswald et al, 1991).

Occasionally, a transbronchial or percutaneous aspirate may yield Langerhans' cells measuring 10 to 12 µm and **resembling macrophages with long cytoplasmic processes. The round or oval nuclei are finely textured and typically have a cleaved or convoluted contour, resulting in an appearance of nuclear creases.** These cells **do not show any evidence of phagocytosis and are CD1a and S-100 positive.** In a classical case, the Langerhans' cells are accompanied by **numerous eosinophils** and lymphocytes; Charcot-Leyden crystals may occasionally be present (see Fig. 19-11C). However, this classic cytologic presentation is uncommon. Most patients have a good prognosis, although some may end with pulmonary insufficiency due to fibrosis and cystic change; thus the importance of an accurate diagnosis (Colby and Lombard, 1983). In most cases, confirmation of the diagnosis will require lung biopsy, which may be successfully performed as a transbronchial biopsy, in at least some instances. For additional discussion, see Chapters 31 and 36.

TABLE 19-1 DIFFERENTIAL DIAGNOSIS OF MORPHOLOGIC MANIFESTATIONS OF VIRAL INFECTIONS IN THE RESPIRATORY TRACT OF MEN					
Epithelial	Cytoplasmic	Nuclear	Multinucleated	Cell	

	Target Cell	Inclusions	Inclusions	Giant Cells	Degeneration
Herpes simplex	Respiratory squamous	No	Yes, ground-glass and eosinophilic	Yes	No
Cytomegalovirus	Respiratory	Yes, eosinophilic or basophilic with halo	Yes, basophilic or eosinophilic, large halo	Occasional	No
Parainfluenza	Respiratory	Yes, eosinophilic with halo	No	No	Yes
Adenovirus	Respiratory	No	Yes, multiple basophilic	No	No
Respiratory syncytial virus	Respiratory	Multiple basophilic with halos	No	100%	Slight
Measles	Respiratory	Multiple small eosinophilic	Rare	100%	Slight

(Modified from Naib ZM, et al. Cytological features of viral respiratory tract infection. Acta Cytol 12:162, 1968.)

SPECIFIC VIRAL INFECTIONS

Over the years, specific cytopathic changes have been described for different viral infections of the respiratory tract. Credit for many of the initial observations goes to Naib et al (1963, 1968). The issue is particularly important for patients with AIDS, who are prone to viral infections that may be treated with antiviral pharmacologic agents. Infectious viruses are obligatory cellular parasites, often forming inclusion bodies as they multiply within cells. Table 19-1, modified from Naib et al (1968), summarizes the principal cytopathic changes attributed to several different, common viral infections identified by culture. Frable et al (1977) described their findings in 33 cases of upper respiratory tract viral infection diagnosed by cytology. A description of cell changes for each specific virus follows.

Herpes Simplex Virus

As discussed in Chapter 10, herpes simplex is a DNA virus related to herpes virus type II, varicella-zoster virus, and to cytomegalovirus. Until a few years ago, herpetic tracheobronchitis and pneumonia had been considered rare disorders affecting markedly debilitated patients. We now know it is not uncommon. Herpesvirus infection has been observed in burn patients (Foley

et al, 1970) and in cancer patients (Rosen and Hajdu, 1971). It is a fairly **frequent cause of respiratory tract disease** that affects children as well as adults, although again, particularly patients with AIDS. At the Montefiore Hospital, 30

P.610

documented cases of herpetic pneumonia were observed during a 2-year period from January 1975 to December 1976, and many more since that time. Yet, while several of the patients had cancer or were immunodeficient, about half had **no clinical evidence of immune incompetence**. Similar observations were recorded by Frable et al (1977). Lindgren et al (1968) observed that herpes virus may be recovered from respiratory secretions of adults without evidence of disease. Clinically, most patients present with **high fever** and **intractable cough**, with or without roentgenologic evidence of pneumonia. Vesicles and ulcerative lesions may be present in the mouth and the upper respiratory tract (Fig. 19-36A).

Cytologic examination of **sputum reveals multinucleated cells with moderately enlarged basophilic nuclei of ground-glass appearance** (Fig. 19-36B), **or nuclei with margination of chromatin and large intranuclear eosinophilic inclusions** (Fig. 19-36C,D). **The nuclei are molded by contact with each other**. There are **no cytoplasmic inclusions**. Herpes virus can be specifically identified in cells and tissues by immunocytochemistry with monoclonal antibody and by in situ hybridization with cDNA (see Chaps. 3 and 4). Most immunocompetent patients recover spontaneously without antiviral therapy.

Figure 19-36 Herpes simplex. *A.* Herpetic tracheitis showing confluent shallow ulcers in the congested mucosa. *B.* A multinucleated cell with nuclear molding and ground-glass nuclei in sputum specimen. *C.* Binucleated bronchial cell with preserved terminal bar and cilia and a single well-formed, homogeneous nuclear inclusion in each nucleus. *D.* Binucleated bronchial cell with nuclear molding, a homogeneous central inclusion within each nucleus, and nuclear clearing about the inclusion with margination of chromatin. (*B,C:* High magnification; *D:* oil immersion.)

It cannot be sufficiently emphasized how essential the cytologic or virologic identification of this

disease is for the patient. **Patients with a history of treated cancer may develop herpetic pneumonia that mimics metastatic tumor. In those patients, a cytologic finding of herpes may prevent unnecessary or even harmful treatment.** It is worth emphasizing that in debilitated patients with advanced stages of cancer or AIDS, herpetic pneumonia may complicate diseases caused by other infectious agents, primarily fungi.

P.611

Varicella-Zoster Virus

Varicella-zoster virus is closely related to the herpes virus. Skin lesions such as varicella (chicken pox) and herpes zoster are caused by this virus. In children, and in patients with AIDS, the virus can cause pneumonia. **Herpes virus-type inclusions** may be observed in epithelial cells of the bronchioles and within the desquamated cells in the alveoli.

Cytomegalovirus

Cytomegalovirus (CMV) is a DNA virus related to herpes. In debilitated infants and immunocompromised patients, the virus may cause a fatal illness.

CMV is characterized in **histologic sections and cytologic specimens** by the presence of **markedly enlarged cells (hence the name) with large, basophilic intranuclear inclusions surrounded by a clear halo, and sometimes, tiny satellite basophilic inclusions in the cytoplasm** (Fig. 19-37A,B). They may be demonstrated in sputum (Fig. 19-37C,D), as first shown by Naib (1963) and Warner et al (1964). While most affected cells are mononuclear, Naib (1963) also noted that the inclusions may be seen in multinucleated giant cells. Epithelial and endothelial cells are involved widely throughout the body, including **bronchiolar and alveolar epithelial cells and macrophages**. In infants, the characteristic inclusions are best demonstrated in exfoliated renal tubular cells in the urinary sediment (see Chap. 22). In patients with AIDS, CMV infection may be associated with multiple other viral and fungal agents. In questionable cases, the virus can be documented by immunocytology with a specific antibody, by in-situ hybridization, or by PCR.

Figure 19-37 Cytomegalovirus (CMV) targets epithelial and endothelial cells, which are enlarged with large nuclei that contain a homogeneous basophilic inclusion with surrounding halo. There may be one or more tiny cytoplasmic inclusions. *A,B.* Histologic sections of lung showing cytomegalovirus inclusions in desquamated cells within alveoli. *C,D.* Sputum with cytomegalovirus inclusions in exfoliated cells. (*C,D:* oil immersion.)

Adenovirus

Koprowska (1961) described **eosinophilic intranuclear inclusions** attributed to adenovirus in respiratory epithelial cells within smears of respiratory secretions. Naib et al (1968) pointed out that **the affected respiratory cells and their nuclei are usually enlarged but retain their cilia. The enlarged nuclei contain multiple spherical eosinophilic inclusions with halos** (Fig.19-38). The **inclusions in some cells merge into a single basophilic mass**. The term **smudge cell** was used to describe them. Pierce and Knox (1960) observed **massive ciliocytophthoria** in adenovirus infection (see above).

Parainfluenza Virus

In children with this viral infection, Naib et al (1968) described **uniform epithelial cell degeneration with**

P.612

ciliocytophthoria of respiratory epithelial cells. There are **multiple eosinophilic cytoplasmic inclusions, but no intranuclear inclusions**.

Figure 19-38 Adenoviral infection: enlarged bronchial cells with preservation of cilia. In the nucleus are multiple round, in reality, eosinophilic inclusions with halos (oil immersion). (Courtesy of Dr. Zuher Naib, Atlanta, GA.)

Respiratory Syncytial Virus

This infection, which can be fatal, **occurs principally in infants or children with primary immunodeficiency**. It may be seen in immunocompromised patients following bone marrow or organ transplant, or after chemotherapy for neoplastic disease. It may occur in normal individuals.

The classical cytologic finding in infections with respiratory syncytial virus (RSV) is the formation of **very large syncytial cell aggregates**, measuring 100 μm or more in diameter (Fig. 19-39). Naib et al (1968) described **multiple, deeply basophilic inclusion bodies with clear halos** within the degenerated cytoplasm of the multinucleated syncytial giant cells. Immunocompromised children with fatal RSV infection typically have a giant cell pneumonia (Hall et al, 1986).

Figure 19-39 Respiratory syncytial virus (RSV). Histologic section of lung from autopsy of an infant who died with RSV bronchitis, showing the large multinucleated syncytial cells in a bronchiole destroyed by inflammation.

In what may have been an earlier stage or more subtle form of the disease, Zaman et al (1996) described one or more discrete **eosinophilic cytoplasmic inclusions in mononuclear pneumocytes** of a BAL specimen from a 45-year-old man who was immunocompromised after stem cell transplantation for multiple myeloma. Multinucleated giant cells were rare. There were no nuclear inclusions and no nuclear molding. Parham et al (1993) also described **pink intracytoplasmic inclusions** in a May-Grunwald-Giemsa-stained BAL specimen of a child with RSV following bone marrow transplantation, confirmed by immunofluorescence and electron microscopy.

Measles (Rubella)

This common infection of childhood is caused by an RNA virus of the paramyxoma family. The infection is usually of a transient nature, but may be fatal in debilitated children in developing countries or in immunocompromised patients regardless of age. The disease is characterized by formation of **multinucleated giant cells (Warthin-Finkelday cells)** that may occur throughout the reticuloendothelial system, mainly in lymphoid tissue and lymph nodes. **Measles pneumonia** is one of the potentially fatal manifestations of the disease.

As early as 1955, Tompkins and Macaulay reported finding **Warthin-Finkelday giant cells in**

nasal secretions before the appearance of other clinical signs of measles such as Koplik's spots and skin rash, an observation later confirmed by Beals and Campbell (1959) and by Mottet and Szanton (1961). It was proposed as a means of early cytologic diagnosis of measles.

The Warthin-Finkelday cells **have up to 100 nuclei and contain spherical eosinophilic intracytoplasmic and intranuclear inclusions**. Similar cells were observed by Naib et al (1968) in material from the respiratory tract and by Abreo and Bagby (1991) in sputum. Harboldt et al (1994) described **two types of giant cells** in an immunosuppressed patient with measles pneumonia: **Warthin-Finkelday giant cells** and **syncytial epithelial giant cells**. The latter are formed by coalescence of hyperplastic alveolar epithelial cells, probably pneumocytes type II, and contain no more than 35 nuclei, whereas Warthin-Finkelday giant cells, which are found throughout the reticuloendothelial system, contain up to 100 nuclei. Both types of giant cells have **intranuclear and intracytoplasmic, sharply demarcated eosinophilic inclusions**.

Polyomavirus

The **homogeneous basophilic nuclear inclusions of polyomavirus**, affecting mainly the urinary tract and the central nervous system, may occur in bronchial cells (Fig. 19-40). The virus may also cause a **fishnet chromatin structure** identical with that seen in urothelial cells (see Chap. 22).

P.613

The pulmonary infection appears to be incidental and has no known clinical significance.

Figure 19-40 Polyoma virus. *A.* Sputum specimen with viral inclusion in bronchial cell. *B.* At higher magnification, the nuclei of affected cells have lost chromatin structure and appear homogeneously basophilic and slightly enlarged. In a later stage of degeneration, the chromatin takes on a coarse “fishnet” structure (*B*: oil immersion).

Human Papillomavirus

Koilocytes, cells that are pathognomonic of a permissive human papillomavirus infection, have been observed in cytologic material derived from **solitary papillomas of the bronchus**. The possible role of the virus in the pathogenesis of solitary bronchial papillomas and in bronchogenic squamous cancer is discussed in Chapter 20. Human papillomavirus in **laryngeal and tracheobronchial papillomatosis** is discussed in Chapter 21.

NONSPECIFIC INTRACYTOPLASMIC INCLUSIONS

Small eosinophilic intracytoplasmic inclusions are not infrequently observed in desquamated bronchial cells of patients with or without cancer. Similar inclusions are commonly

seen in cells of the urinary sediment (see Chap. 22 for further discussion of their nature). The **eosinophilic cytoplasmic inclusions seen in ciliocytophthoria** (see above) are morphologically similar. These inclusions represent degenerative cytoplasmic aggregates of intermediate filaments and have no diagnostic significance. They should not be confused with viral inclusions. It has been suggested that such inclusions are more numerous in the presence of metastatic urothelial cancer. This has not been our experience.

PULMONARY MYCOSES

Although lung diseases caused by fungi have been known for many years in endemic areas, the movements of populations, treatment of patients with immunosuppressive agents, and mainly the onset of AIDS have significantly increased the prevalence of this group of diseases in the US and other countries. **Many of the organisms can be identified in routinely Papanicolaou-stained cytologic material from the respiratory tract**, although some require culture or special staining procedures for identification. Sputum or BAL specimens are commonly used for diagnosis, and fiberoptic bronchoscopy with BAL cytology is reported to approach 90% sensitivity; together with transbronchial biopsy, diagnostic yield has been as high as 98% (Broaddus, 1985). With the availability of new drugs, the proper identification of these organisms has become an urgent, potentially lifesaving task.

Pathogenic Fungi

This group of fungi is primary pathogens (i.e., they are capable of causing disease in otherwise normal, healthy persons). Only a few of the most common and most important organisms seen in cytologic preparations will be discussed here. The reader is referred to other sources for more extensive description.

Cryptococcus neoformans (hominis)

Once uncommon, cryptococcal infections are now **frequently observed in AIDS, and occasionally in immunosuppressed leukemic patients**. The diagnosis is of considerable clinical importance. While the disease typically presents as a **meningitis** (see Chap. 27), the lung is believed to be the site of entry for the fungus (see below); hence, its **early detection and treatment may prevent dissemination**.

Histology

Lung involvement may be **diffuse or localized**. In the **diffuse form**, as the organism extends throughout the alveolar space, its thick mucoid capsular material **can suggest pulmonary alveolar proteinosis**. In its **localized granulomatous form, the fungal lesions can mimic bronchogenic carcinoma** (Fig. 19-41A). The cryptococcal infection in

P.614

lung and particularly in meninges has a characteristic sticky mucoid appearance that should suggest the proper diagnosis on gross examination.

Figure 19-41 *Cryptococcus*. *A*. Gross photograph of cryptococcal pneumonia, which has a greywhite mucoid appearance and may mimic a mucinous lung cancer. *B*. A cluster of cryptococcal spores in sputum under high magnification. Note that the thick capsule is only faintly stained by the Papanicolaou stain. *C*. Narrow-based budding of *Cryptococcus* (arrow). *D*. Cryptococcal yeast varies in size; some are phagocytized by macrophages, others lie free. The capsules stain red with mucicarmine. (*B-D*: Oil immersion.)

Cytology

The **spherical yeast form of the organism**, as it is seen in the sputum, varies greatly in size from 5 to 25 μm in diameter, and has a thick, sharply demarcated **transparent capsule** (Fig. 19-41B). It produces a single, **teardrop-shaped bud (spore) attached to the mother cell by a narrow pedicle** (Fig. 19-41C). The organisms are faintly stained in both Papanicolaou and Diff-Quick stains. They may be found free or phagocytized within mononuclear alveolar macrophages or multinucleated giant phagocytes (Fig. 19-41D). **The thick mucoid capsule stains with mucicarmine (Fig. 19-41D), periodic acid-Schiff (PAS), and Gomori methenamine silver stains, facilitating identification in sputum as in spinal fluid** (see Chap. 27). In fresh sputum specimens, the organisms can be stained supravitaly with 1% cresyl blue in distilled water and counterstained with Sudan IV in 70% alcohol (Beemer et al, 1972).

Blastomyces dermatitidis

Pulmonary blastomycosis caused by *Blastomyces dermatitidis* was described in detail by Johnston and Amatulli (1970). The disease, observed mainly in young people, produces **granulomatous lesions and abscesses** in the skin. The fungus may also **involve the lungs wherein it causes pneumonias that can mimic bronchogenic carcinoma**. It may be fatal if untreated. **Primary diagnosis of this disease by cytologic examination of sputum** should be the rule.

In sputum, the **yeast forms of the organism are spherical, about the same size or larger than *Cryptococcus***, from which they differ by absence of the thick, mucoid capsule (Fig. 19-42A). **The organism has a refractile, thick wall, stained by methenamine silver (Fig. 19-42B)**. It **produces single buds, which are often rounded and are attached to the mother cell by a broad, flat surface**. The form of the bud and its attachment differ from the teardrop-shaped bud of *Cryptococcus*. The organisms may be phagocytized by macrophages or found free. Other forms of blastomycosis have not been reported in cytologic material.

Coccidioides immitis

Coccidiomycosis, previously endemic to the San Joaquin Valley in California, the western and southwestern regions of the US, and Central and South America, now has a worldwide distribution. In New York State, there have been approximately 30 cases a year for the last 5 to 10 years,

P.615

almost all in immunodepressed individuals who have traveled to endemic areas (Chaturvedi et al, 2000). The **pulmonary form of the disease** produces **infiltrates that may be pneumonic, may mimic tuberculosis because of cavitory lesions, or may present as a lung mass that can simulate a neoplasm**. In most cases, primary infections are asymptomatic and the disease is self-limiting; but in a small percentage of patients, progressive generalized forms of the disease may occur.

Figure 19-42 Blastomycosis. *A.* Sputum with two blastomyces yeast in a macrophage. *B.* Blastomyces are stained by Grocott silver stain. Note the cluster of organisms, which were engulfed by a phagocytic giant cell, not well shown. There are other extracellular organisms, including one with broad-based budding.

The organism in sputum has been described by Naib (1962), Guglietti and Reingold (1968), and Johnston (1992) as **large spherules with thick walls, measuring from 20 to 100 μm in diameter. Minute endospores may be observed within the spherule in sputum** (Fig. 19-43A), often more readily than in histologic sections. The endospores stain reddish in Papanicolaou stain (Guglietti and Reingold, 1968). Rosenthal (1988) observed the organisms in **FNA** of cavitory lesions; and Raab et al (1993) described and illustrated the cytologic findings in 73 patients diagnosed by FNA. They noted large amounts of granular, eosinophilic debris in the smears, with a paucity of inflammatory cells. Many of the spherules had a crushed or fractured appearance, and some were calcified.

Figure 19-43 Coccidiomycosis. *A.* Large thick-walled spherule in sputum, almost as large as an intermediate squamous cell, containing endospores. *B.* Methenamine silver stain of same specimen. (Case courtesy of Ms. Carol Bales and Ms. Gretchen Torres.)

Paracoccidioides brasiliensis

Paracoccidiomycosis is endemic to Brazil and other parts of South America. The fungus *Paracoccidioides brasiliensis* is characterized by large spores surrounded by multiple peripheral buds, sometimes described as a ship's wheel (Fig. 19-44). Tani and Franco (1984) examined sputum and bronchial cytology specimens from **45 patients with lung involvement** and were able to identify the organism in Grocott-stained specimens from 43 of the 45 patients, primarily in cell block sections. Most of the specimens were purulent or hemorrhagic and contained epithelioid cells and multinucleated giant cells within inflammatory exudate. They concluded that cytology was an effective diagnostic technique for this infection.

Histoplasma capsulatum

Histoplasmosis is seen predominantly in the southern states and the Ohio and Tennessee valleys. Many organs of

P.616

the body may be affected. The **pulmonary forms** of the infection **can mimic tuberculosis** and may be a cause of **sclerosing mediastinitis**.

Figure 19-44 Paracoccidiomycosis: Thick-walled spherules with peripheral buds resembling the spokes on a ship's wheel (high magnification).

The **tiny organisms** (2 to 4 μm in diameter) are best recognized when seen within the **cytoplasm of a macrophage**, which they may fill with **tiny dot-like structures with clear halos** (Fig. 19-45). Johnston (1992) reported great difficulty in identifying this organism in sputum, and without special stains such as the Grocott methenamine silver stain, it is virtually impossible. The disease is not uncommon in AIDS patients (Salzman et al, 1988; Tomita and Chiga, 1988) and when suspected, the organisms are best demonstrated by silver staining of BAL specimens. (Blumenfeld and Gan, 1991).

Sporothrix schenckii

Pulmonary **sporotrichosis** is uncommon. Clinically, it may mimic tuberculosis, but there are no specific signs or symptoms.

Farley et al (1991) described finding **multiple, small (2-4 μ m) ovoid, eosinophilic intracytoplasmic yeast in macrophages** of Papanicolaou-stained sputum from two patients with culture-confirmed sporotrichosis. Gori et al (1997) reported making this diagnosis by sputum cytology in an HIV-infected patient.

Figure 19-45 Histoplasmosis: Numerous tiny dot-like yeast with clear halos are seen here engulfed by histiocytes in the spleen. They measure about 2 μ m (oil immersion).

The yeast has a nonstaining cell wall, giving the appearance of a thin halo. They closely resemble *Histoplasma capsulatum*, from which they may be differentiated by their tendency to form **elongated, budding cigar bodies 2 to 3 μ m thick and up to 10 μ m in length**. Hyphae formation at body temperature is unusual. This fungus should not be confused with *Candida albicans*, which is extracellular and often forms pseudohyphae (see below).

Rhinosporidium seeberi

Rhinosporidiosis is primarily an infection of the nasal mucosa and upper respiratory tract, endemic in parts of India, Central, and South America. In tissues, the **fungus is in the form of a large sphere or sporangium measuring 25 to 300 μ m in diameter. The sporangium has a thick homogeneous wall and clear cytoplasm containing many small endospores**.

The fungus cannot be cultured, and diagnosis requires direct examination of tissue or cell samples. Gori and Scasso (1994) reported cytologic findings in two cases.

Opportunistic Fungi

The opportunistic fungi that are normally found as saprophytes may become pathogenic in debilitated or immunocompromised patients. Masses of such fungi may inhabit bronchi as **fungus balls (mycetomas)** for prolonged periods, and may cause significant atypias of the bronchial lining that can lead to an erroneous diagnosis of cancer, as illustrated below. The error may be compounded by the radiologic presentation of a single pulmonary lesion mimicking cancer.

Fungi of the class **Phycomycetes**, which include **Aspergillus** and **Mucor species**, are widely distributed in nature and can produce an alarming and often **deadly form of pneumonia** in susceptible individuals. They have a propensity to invade pulmonary vessels, thereby causing infarction, necrosis, and abscess formation (**phycomycosis**). Organs such as the **orbit** and **brain** can be infected as well. This dramatic clinical picture with its ominous prognosis, has now been recognized as a **fairly frequent complication of intensive multiagent chemotherapy** of cancer and **in AIDS** patients. Chest x-rays may show pneumonic consolidation, solitary or multiple nodules or masses, and cavitation with or without intracavitary masses (mycetomas) (McAdams et al, 1997).

Candida albicans (Monilia or Thrush)

Budding yeast and/or **pseudohyphae** of *Candida* may be observed in specimens taken from the **oral cavity** or **vagina** where the warm, moist environment provides ideal growth conditions (see Chaps. 10, 15, and 21). In well patients, it is usually considered an innocuous tenant. In immunosuppressed or debilitated patients, and not infrequently in terminal cancer patients, **it may become invasive and disseminated**,

P.617

causing urinary tract and pulmonary infections (Fig. 19-46), and sometimes septicemia with endocarditis. Its presentation in sputum and other pulmonary specimens is as described in other sites (see the chapters cited above).

Pseudohyphae of monilia must be differentiated from hyphae of *Trichoderma* sp, a common contaminant (Fig. 19-46B).

Aspergillus Species (Aspergillosis)

Aspergillus may produce a **diffuse pulmonary infection or solitary lung lesions (so-called solitary aspergilloma)**, observed mainly in debilitated and AIDS patients. It has a strong tendency to invade blood vessels with infarction and necrosis of tissues, and cavitation harboring a fungus ball (mycetoma). Early cytologic diagnosis of aspergillosis leading to effective treatment may be life-saving.

Microscopic Features

The **rigid, thick, brown, septate hyphae of the fungus** are readily identified when present in sputum or bronchial wash specimens (Fig. 19-47A). The **hyphae branch at an angle of approximately 45°**, one of the features that differentiates this fungus from the *Mucor* species (see below). Under proper aerobic conditions, **fruiting heads or conidiospores** will be formed (Fig. 19-47B).

A characteristic feature of aspergillosis, mainly with the species *Aspergillus niger*, is the formation of calcium oxalate crystals, first reported in cytologic material by Reyes et al (1979). The crystals, which may be observed in sputum, bronchial washings, BAL, and pleural fluid are colorless, sheaf-shaped structures that are strongly birefringent under polarized light. Presence of the crystals alone, even if the organism cannot be identified, is highly suggestive of aspergillosis. The **differential diagnosis** includes the **rhomboid, birefringent crystals of barium sulfate**, once used as a roentgenographic contrast medium (Shahar et al, 1994), and the very rare **intracellular calcium crystals** observed by Vigorita et al (1979) in a patient with tuberculosis.

Thick-walled bronchiectatic or abscess cavities containing fungus balls (mycetomas) (Fig. 19-47C) may be surfaced by atypical metaplastic squamous epithelium (Fig. 19-47D) or ragged reactive hyperplastic basal epithelium (Fig. 19-47E,F).

Figure 19-46 A. *Candida*. Spores and pseudohyphae growing in the bronchial mucosa. See other chapters for additional illustrations. B. *Trichophyton* sp, a common cause of dermatophycomycosis and a contaminant in saliva resembling candida pseudohyphae (A,B: High magnification).

Mucor Species (Mucormycosis)

This family of fungi, like *aspergillus*, is **capable of invading blood vessel walls and causing vascular thromboses and infarcts** (mucormycosis). Its principal representative is *Mucor*, but several other related fungi may cause disease (Johnston, 1992). Infection with *Mucor* occurs in diabetics and in debilitated or immunocompromised patients.

The fungi are recognized by **broad, ribbon-like, nonseptate hyphae of variable diameter** that branch at 90° (Fig. 19-48). Unlike *Aspergillus*, the hyphae are wavy and folded. The organism has been identified in sputum, bronchial brushings, and BAL.

Pneumocystis carinii

Pneumocystis carinii, a ubiquitous organism, has assumed a major role in pulmonary pathology and cytology since the onset of AIDS. Because of its microscopic appearance, the organism was long considered to be a protozoan parasite, although its molecular biologic features now indicate that it is a fungus (Edman et al, 1988). The mature organism forms **small cysts**, measuring 4 to 6 μm in diameter, **containing tiny trophozoites** that, upon rupture of the cyst, are released, and in turn, mature to form new cysts. Before the onset of AIDS, **pneumonia caused by *P. carinii*** was only occasionally observed in **debilitated infants and immunocompromised adults**. Today, it is often the **first and dominant major complication of AIDS**. The clinical presentation of *P. carinii* pneumonia is highly variable, ranging from minimal pulmonary infiltrate to rapidly progressive and extensive pneumonia. Because recovery depends on prompt treatment, rapid diagnosis is essential.

Once the disease is suspected in an immunodeficient patient, either because of respiratory symptoms or clinical signs, BAL specimens are generally recommended for diagnosis (Stover et al, 1984; Broaddus et al, 1985). Bronchial

P.618

brushing is of limited additional value (Djamin et al, 1998). **BAL has almost completely replaced open lung biopsy, which was previously considered necessary for diagnosis.** While the organisms also may be found in spontaneous or induced sputum (Bigby et al, 1986), and in bronchial washings, they are generally few and difficult to identify.

Figure 19-47 Aspergillus. A. Aspergillus in sputum showing septate, rather rigid hyphae branching at an acute angle. B. Fruiting head of aspergillus identified at autopsy, a response to aerobic conditions. (Case courtesy of Dr. M. B. Zaman.) C. Thick-walled abscess cavity with aspergilloma. Both halves of the cavity are shown. D. Atypical squamous metaplasia of the cavity wall shown in C. E. Markedly inflamed wall of another bronchiectatic cavity containing an aspergillus fungus ball (aspergilloma). The lumen is lined by irregular reactive basal epithelial cells. Elsewhere, there was marked basal cell hyperplasia. F. A cluster of small, dark, tightly packed basal epithelial cells in bronchial washings from the same patient prior to surgery. The cells are consistent with origin from the lining epithelium illustrated in E. (B: High magnification.) (E and F from Koss and Richardson, 1955.)

Cytology

The *P. carinii* organisms themselves are not easily identified in conventional smears with the Papanicolaou or Diff-Quick stain, though their very likely presence is signaled by the finding of **finely vacuolated or foamy proteinaceous alveolar casts** in bronchial wash specimens (Naimey and Wuerker, 1995).

P.619

In the proper clinical setting, these casts are essentially diagnostic of *Pneumocystis* infection (Fig. 19-49A). The cysts, which are unstained by conventional cytology stains, account for the vacuoles found in the casts. They are **spherical, oval, or cup-shaped structures with one flat surface, measuring 4 to 6 μ m in diameter. Within the cysts, one or two tiny dot-like trophozoites or sporozoites, measuring 0.5 to 1 μ m in diameter, may be seen** (Sun and Chess, 1986). The trophozoites that are released from a cyst appear as numerous small dots. **The walls of the cysts and the trophozoites** are stained and readily identified by the Grocott methenamine silver (GMS) or Gram-Weigert stain (Fig. 19-49B,C).

Figure 19-48 Mucormycosis. *A.* Bronchial aspirate with mucormycosis in a patient with malignant lymphoma. *B.* Mucormycosis in brushing cytology of upper respiratory tract from an immunosuppressed patient with kidney transplant. The hyphae are folded and wavy, flat and broad compared with aspergillus, and nonseptate. They branch at right angles compared to the rigid, acute angle branching of aspergillus. (*A,B*: High magnification.)

Figure 19-49 *Pneumocystis carinii*. *A.* Bronchial wash specimen showing a proteinaceous cast of an alveolus containing many tiny vacuoles. The vacuoles are due to the presence of unstained *Pneumocystis* cysts. The Grocott methenamine silver stain (*B*) or Gram-Weigert stain (*C*) may be used to stain the cysts.

P. carinii also can be visualized in unstained or Papanicolaou-stained slides by their **bright yellow fluorescence** under the fluorescence microscope (Ghali et al, 1984; Chandra et al, 1988), but this diagnostic technique is seldom used. It should be noted that **the walls of cryptococci also**

P.620

are fluorescent (Sun and Chess, 1986), but the size and configuration of the *P. carinii* organisms are quite different. A number of **monoclonal antibodies to *P. carinii*** are now available for immunocytologic identification of the organisms (Kovacs et al, 1986; Blumenfeld and Kovacs, 1988; Elvin et al, 1988). Kovacs et al (1988) reported over 90% sensitivity and 100% specificity in the immunocytologic diagnosis of *P. carinii* in induced sputum samples. The

more sensitive **PCR** technique has been described recently by the same group (Olsson, 1996); but it may be too sensitive, picking up cases in which these ubiquitous organisms are present without infection. In a comparison of immunofluorescence and PCR with direct staining techniques, Armbruster et al (1995) favored a combination of the **Diff-Quick stain and the fluorescent dye, Fungifluor**. For the present, we find the **methenamine silver staining technique** on **BAL** specimens to be our diagnostic method of choice.

Figure 19-50 *Allescheria boydii*. Pulmonary mycetoma caused by *Allescheria boydii*. *A*. Composite photograph of cell abnormalities found in the patient's sputum. These were thought to represent squamous cancer. Cyst lining, partly well differentiated (*B*) and partly atypical squamous epithelium (*C*). The causative organism: conidia on conidiophores (*D*) and a tuft of conidiophores (*E*). (From Louria DB, et al. Pulmonary mycetoma due to *Allescheria boydii*. Arch Intern Med 117:748-751, 1966.) (*D*: oil immersion.)

***P. carinii* trophozoites must be differentiated from**

P.621

histoplasma, which does not form cysts, has a more uniformly round configuration, and does not present in clusters. Because histoplasma elicits a granulomatous reaction, it is very rarely seen in sputum or BAL specimens. The differential diagnosis is more important in histologic sections than in cytologic samples.

Alternaria

This species was discussed as a contaminant (see above). It may be a cause of hypersensitivity pneumonitis in woodpulp workers (Schleuter et al, 1972) and can rarely cause pulmonary granuloma (Lobritz et al, 1979).

Cytology of Mycetomas

Mycetomas are fungus balls lodged in a bronchiectatic cavity. The markedly inflamed, thick wall of an aspergilloma cavity (see Fig. 19-47C) can simulate a cavitating carcinoma on x-ray. The **epithelial lining of such a cavity** may undergo reactive basal cell hyperplasia and squamous metaplasia with **marked atypia that may lead to a diagnostic error in cytologic samples**. Figures 19-47E and F illustrate an early case in which cells shed from the reactive basal cell hyperplasia surfacing an aspergilloma cavity were mistakenly interpreted as small-cell carcinoma (SSC).

In our experience, the most striking cytologic abnormalities were seen in a case of pulmonary mycetoma caused by *Allescheria boydii*, reported by Louria et al (1966). This patient with an unusual, clinically suspect solitary lesion of the right upper lobe of the lung had **markedly abnormal squamous cells in specimens of sputum** on several occasions, resulting in an erroneous diagnosis of squamous cancer (Fig. 19-50). The fungus ball lay within a solitary cyst that was lined in part by well-differentiated squamous epithelium and in part by highly atypical epithelium from which the abnormal cells undoubtedly originated. There are few safeguards to prevent such errors occurring from time to time.

Opportunistic Organisms as Contaminants

Opportunistic fungi and certain other organisms are common contaminants in specimens of sputum, some because they are saprophytic inhabitants of the mouth and oropharynx and others derived from air or water during collection and processing. How very common they are was demonstrated by my colleague, Dr. M. B. Zaman, in an unpublished study of the sputum specimens obtained from men enrolled in the Early Lung Cancer study described in Chapter 20. Zaman examined the sputum specimens from 4,968 male cigarette smokers who were followed for 5 to 8 years with examinations of sputum cytology scheduled every 4 months. Ninety percent of the men had five or more sputum specimens examined. The most common organisms of interest were *Actinomyces*, *Candida*, and *Aspergillus* (Table 19-2); less commonly found organisms are listed in Table 19-3. Obviously, the mere presence of these organisms in sputum of a patient with or without symptoms of pulmonary disease is no guarantee that the organism is causative of infection.

TABLE 19-2 OPPORTUNISTIC ORGANISMS COMMONLY FOUND IN SPUTUM SPECIMENS OF CIGARETTE-SMOKING MEN		
Organism in sputum	No. men with opportunistic organisms	
	With lung cancer (154)	No lung cancer (4814)
<i>Actinomyces</i>	145 (94%)	4586 (95%)
<i>Candida</i>	61 (40%)	1605 (33%)
<i>Aspergillus</i>	5 (3%)	68 (1.4%)

PARASITES

Amoebiasis

Entamoeba histolytica was identified in sputum by Kenney et al (1975) in a case of amoebiasis involving the lung. The parasite was identified by its characteristic nucleus and

P.622

phagocytized erythrocytes (Fig. 19-51). Other usually saprophytic amoebae have been recovered in sputum and in BAL specimens from immunocompromised patients (Newsome et al, 1992).

Trichomoniasis

Trichomonas buccalis (*T. elongatus*) is a common inhabitant of the oral cavity in conditions of poor hygiene. Walton and Bacharach (1963) reported finding trichomonads in three specimens from the respiratory tract, but did not classify them further. It is not known whether the organisms were an oral contaminant. (See also a report by Osborne et al, 1984.) Trichomonads are described in detail in Chapter 10.

Strongyloidiasis

The larval form of the small nematode *Strongyloides stercoralis* (threadworm) penetrates the victim's skin and achieves wide circulation through the bloodstream before maturing and settling in the small intestine. **Autoinfection** by larvae produced in the intestine is common and accounts for the **hyperinfective forms of this disease**, usually under poor hygienic conditions and in the immunodeficient patient. The case described by Kenney and Webber

(1974) occurred in an immunocompetent person, but the 32 fatal cases described by Purtilo et al (1974) were in patients with a wide variety of disorders including malignant tumors, burns, radiation exposure, and other debilitating diseases in which the common denominator was reduced cell-mediated immunity. It must be emphasized that only two people in this group of patients had blood eosinophilia.

Cytology

There are several reports of cytologic diagnosis of strongyloidiasis in sputum, summarized by Johnston (1992). Examination of **sputum** may lead to early diagnosis and treatment of this potentially fatal disorder. In one striking example that we observed, the **fresh sputum specimen was quivering** due to movement of the **filariform larvae** in the case of a patient with hyperinfective disease (Fig. 19-52A,B). The larvae have a worm-like configuration, with a thick, rounded forward end and a characteristic **V-shaped notch at the sharply pointed tail end of the filiform**. The noninfective **rhabditiform larvae** with cross striations of the body may also be recognized (Fig. 19-52C) (Humphreys and Hieger, 1979).

Figure 19-51 *Entamoeba histolytica*. Cell block of sputum in a patient with intestinal amoebiasis and lung abscess. The organism may be identified by the characteristic round eccentric nucleus, with a central karyosome and finely granular nuclear material. (From Kenney M, et al. Amebiasis. Unusual location in lung. NY State J Med 75:1542-1543, 1975. © Medical School of the State of New York.)

***Ancylostoma Duodenale* (Hookworm)**

Acute superinfection with hookworm is uncommon, and hookworm larvae in sputum have not been reported to date. A variety of filariform organisms not further identified but commonly present in drinking water may closely resemble them (see Fig. 19-18B,C). With knowledge of the clinical setting, there should be no difficulty in recognizing these as contaminants.

Echinococcus

Lung cysts caused by the larval form of the **tapeworm *Echinococcus granulosus* or *E. multilocularis* (hydatid cysts)** are endemic in Europe and Asia. Oztek et al (1997) found scolices of the tapeworm in Papanicolaou-stained sputum or bronchial washings/brushings from 11 of 111 patients in Turkey with histologically proven hydatid cysts, and hooklets in specimens from 26 patients. The disease is being seen with increased frequency in the US. Allen and Fulmer (1972) reported identifying the **scolex of the parasite with its characteristic hooklets in the sputum** of a patient with the disease and two cases were reported by Tomb and Matossian (1976) (Fig. 19-53A). A case diagnosed by FNA biopsy of lung was reported by Koss et al (1992).

Giardia lamblia

The presence of this gastrointestinal parasite in **BAL** fluid was reported by Stevens and Vermeire (1981). It is commonly found in biopsies of duodenum, and may be seen in cytologic specimens (see Chap. 24).

Lung Flukes

Paragonimus westermani is a common invader of the lung in parts of East Asia, namely in Korea, parts of China, Thailand, and Indonesia. The infection is acquired by eating uncooked, infected shellfish. The **pulmonary lesions clinically resemble chronic tuberculosis** and may form **cavities** that communicate with the bronchus. Generalized spread of the infection to other organs, including the brain, may occur and can be fatal. The parasite is identified by **finding ova in the sputum**, which is typically blood-tinged and contains many leukocytes, including **eosinophils**, and **Charcot-Leyden crystals**. The **ova measure about 100 µm in their long axis, and have a thick, yellowish-brown,**

P.623

oval shell with a more thickened, distinctly flattened end or operculum (Fig. 19-53B).

Figure 19-52 *Strongyloides stercoralis*. A. Unstained sputum specimen from a 69-year-

old man with hyperinfection complicating lung cancer. The microfilaria were readily visualized in sputum that was literally quivering on the slide due to their vigorous movement. *B.* Stained specimen. One can just make out the blunt, rounded, forward end and bifid sharp tail. *C.* In another patient, the rhabditiform larvae were found in sputum (and in spinal fluid). Note the cross-striations. (*B,C:* H&E Stain.)

Willie and Snyder (1977) reported finding the ova in bronchial washings, and McCallum (1975) in fluid from a lung cyst. Rangdaeng et al (1992) identified the ova in a **FNA of a lung abscess** from a 19-year-old Nigerian woman with a history of prior treatment for lymphoma of the breast.

Microfilariae

Filariasis is a common disease in developing countries, but rare in the US and Europe. Avasthi et al (1991) reported a patient from India in whom the diagnosis of Bancroftian microfilariasis was made by FNA of the lung from a 25-year-old man who had coexisting pulmonary tuberculosis. See also reports by Anupindi et al (1993) and Walter et al (1983) describing various species of filariae in pulmonary material.

Figure 19-53 *A. Echinococcus granulosus.* Scolex with hooklets in an FNA specimen that penetrated the right lower lobe of lung and entered a hydatid cyst of the liver. *B. Paragonimus westermani* ovum. (Case courtesy of Nancy Morse.) (*A:* H&E stain; *A,B:* High magnification.)

Dirofilariasis

Dirofilaria immitis, the dog heartworm, may be transmitted to humans by mosquitoes. The microfilaria are carried

P.624

through the venous circulation to the lung where they die, causing small **peripheral infarcts** and **granulomas**. Akaogi et al (1993) reported a case of pulmonary dirofilariasis in which transbronchial brushing cytology yielded **papillary bronchiolar epithelium with high nuclear/cytoplasmic ratio, macronucleoli and nuclear irregularity mimicking carcinoma**. The organism was not identified.

Microsporidia

Intestinal microsporidiosis caused by tiny intracellular parasites of the **Microsporidians** family is an important cause of **debilitating diarrhea** and weight loss in immunodeficient **AIDS patients (Weber et al, 1994)**. The organism rarely involves the lung and only a small number of such cases have been reported in patients with disseminated disease (Lanzafame et al,

1997; Scaglia et al, 1998; Schwartz et al, 1993). Remadi et al (1995) identified **microsporidian spores, measuring about 1.5 μ m, within macrophages in BAL specimens from an AIDS patient**. The tiny spores are not easily seen in Papanicolaou-stained preparations, but may be visualized with a fluorescent mycology stain or by immunofluorescence antibody staining.

OTHER BENIGN DISEASES AND CONDITIONS OF THE RESPIRATORY TRACT

There are a few other conditions of the respiratory tract in which cytologic techniques may contribute to the diagnosis and treatment.

Alveolar Proteinosis

Pulmonary alveolar proteinosis, first described by Rosen et al in 1958, is now understood to be a disease of impaired macrophage function. The disease may be primary and idiopathic or secondary to infections, hematologic disorders, inhaled fumes, or inorganic dusts. In its most common acquired form, it is an autoimmune disorder caused by antibodies targeting cell surface receptors for granulocytemacrophage colony stimulating factor, which is expressed on alveolar macrophages. Most patients present with insidious onset of progressive exertional dyspnea and cough; the 5-year survival rate is about 75% with deaths due to respiratory failure or uncontrolled infection. **Biopsies of the lung show preserved alveolar architecture with alveoli filled by phospholipid-rich proteinaceous material** that ultimately blocks respiratory exchange and may lead to the death of the patient (Fig. 19-54A).

There is good evidence that the material filling the alveoli is surfactant, probably due to defective removal by alveolar macrophages (Golde et al, 1976) rather than excess production by type II pneumocytes (see Trapnell et al, 2003, for a recent review). BAL has been the treatment of choice, and it provides symptomatic relief, improved physiologic and radiologic findings, and increased survival.

Sputum of patients with pulmonary alveolar proteinosis has been studied by Carlson and Mason (1960), Burkhalter et al (1996), Mermolja et al (1994), and by the late Dr. M. Wilson Toll in our laboratories (unpublished data). The presence of **chunks or globules of amorphous or fibrillar PAS-positive proteinaceous casts** containing or associated with cellular debris, macrophages and inflammatory cells is **suggestive of this disease in the proper clinical setting**. It is not diagnostic, and Toll has pointed out that **very similar material may be observed in sputum of patients with other chronic lung disorders** (Fig. 19-54B).

The diagnosis considered clinically can be confirmed by BAL (Martin et al, 1980). BAL specimens are opaque, muddy or milky in appearance. Smears and cell block sections contain granular, lipoproteinaceous, eosinophilic material that may be mistaken for mucus or casts of *P. carinii*. It is **brightly stained in the PAS reaction**, with or without diastase digestion, and contains **large, foamy alveolar macrophages with PAS-positive cytoplasmic inclusions** and a few inflammatory cells of other types. Surfactant proteins have been demonstrated by immunohistochemical stains (Wang et al, 1997; Schoch et al, 2002); and multilamellar osmiophilic bodies and tubular myelin, similar to condensed surfactant, have been demonstrated in the alveolar material by electron microscopy (Sosolik et al, 1998).

Malakoplakia

Malakoplakia is a rare enzymatic disorder of **macrophages that have an impaired ability to process and digest coliform bacteria, which accumulate in lysosomes**. The peculiar granulomas that characterize the disease are composed of epithelioid histiocytes with abundant cytoplasm that contains **concentrically laminated bodies (Michaelis-Guttman bodies)**, rich in calcium and iron, formed on enlarged lysosomes containing residual bacteria. The granulomas are located in the bronchial wall subjacent to the epithelium and may be identified

in **bronchial brushings that disrupt the epithelium, releasing characteristic epithelioid macrophages with Michaelis-Guttman bodies** (Fig. 19-55C). Malakoplakia was first observed in the urinary bladder as umbilicated soft yellow plaques (from Greek, *malakos* = soft, hence, soft plaque). It is described in detail in Chapter 22. Two cases of bronchial malakoplakia that we encountered are illustrated in Figure 19-55. Schwartz et al (1990) and Shin et al (1999) reported cases diagnosed by transbronchial biopsy; and Sughayer et al (1997) and Lambert et al (1997) reported cases diagnosed by percutaneous FNA. The causative organism in all these cases was *Rhodococcus equi*.

Rheumatoid Granuloma

Rheumatoid granulomas may occur in the lung and pleura. Although there is a classic cytologic presentation of rheumatoid pleurisy in effusions (see Chap. 25), only very limited information is available on the cytologic findings in sputum or bronchoalveolar specimens. Johnston and Frable (1979) described one patient in whom bronchial washings disclosed necrotic material and cells of uncertain derivation, possibly epithelioid macrophages. Kolarz et al (1993) reported that patients with rheumatoid arthritis had an increased number of activated (HLA-DR+) helper (CD4) lymphocytes in BAL specimens, which was most marked in patients with lung involvement.

P.625

Figure 19-54 Pulmonary alveolar proteinosis. *A.* Histologic section showing structurally intact alveoli filled with dense protein precipitate. There is very little cellular reaction. *B.* Protein cast, mimicking proteinosis. Proteinaceous material observed in a cell block of sputum (high magnification). There was no evidence of pulmonary proteinosis, which is a frequent finding.

Figure 19-55 Malakoplakia. *A.* Subepithelial bronchial nodule composed of large epithelioid histiocytes with abundant eosinophilic cytoplasm. *B.* Careful inspection at higher magnification reveals Michaelis-Guttman bodies within the cytoplasm of some epithelioid cells. *C.* Bronchial brush cytology specimen showing epithelioid cells with intracytoplasmic Michaelis-Guttman bodies. *D.* Bronchial malakoplakia in a 15-year-old girl with congenital AIDS. A Gram stain showed the bacteria *Rhodococcus equi* within the epithelioid histiocytes. (A-C: Courtesy of Dr. Timothy Greaves, Los Angeles, CA.)

P.626

Gaucher's Disease

Gaucher's disease is a **familial disorder of lipid metabolism**, caused by a defective enzyme, glucocerebrosidase, resulting in an accumulation of faulty glucocerebrosides in various organs, mainly the liver, spleen, and bone marrow. The disease may be observed in infants, juveniles, or adults and is diagnosed by recognition of the characteristic large macrophages that store the cerebroside.

Gaucher's disease involving the lung was described by Schneider et al (1977) and diagnosed by aspiration biopsy of a pulmonary infiltrate by Johnston and Frable (1979). Carson et al (1994) identified Gaucher cells in a BAL specimen from a child. **The characteristic Gaucher cells in this type of specimen resemble mononuclear pulmonary macrophages with small eccentric nuclei and abundant striated and finely vacuolated cytoplasm.** An example of Gaucher cells is illustrated in Chapter 38. They may be superficially similar to the foam cells of lipid pneumonia but have **striated and strongly PAS-positive cytoplasm** (due to accumulated cerebroside), and numerous irregular lysosomes by electron microscopy.

Inflammatory Pseudotumor (Sclerosing Hemangioma)

These uncommon benign lesions form a well-delineated pulmonary mass that can mimic lung cancer on x-ray. They occur mainly in adolescents and young adults. There are several histologic variants: some of the lesions are composed predominantly of proliferating fibroblasts (**benign fibrous histiocytoma type**), and some predominantly of inflammatory cells, often with a dominant plasma cell component (**plasmacytoma type**). This diversity of histologic patterns resulted in a number of different names attached to these lesions, among which are **sclerosing hemangioma, benign fibrous histiocytoma, plasmacytoma, and granulomatous inflammatory lesions.**

Figure 19-56 Inflammatory pseudotumor. A,B. An FNA of a pseudotumor of lung in a 40-year-old man demonstrates a mixed pattern of spindly fibroblasts, histiocytes, and variable numbers of plasma cells. The appearance is that of a chronic inflammatory process (high magnification).

We have observed several examples of this lesion diagnosed by percutaneous lung aspiration (Koss et al, 1992). Smears of the aspirates from the **benign fibrous histiocytoma type** disclosed **loosely structured bundles of slender fibroblasts and single, slender fusiform cells**, accompanied by scattered inflammatory cells (Fig. 19-56A,B). In the **plasmacellular type**, the smears disclosed mainly **plasma cells in company of macrophages and scattered fibroblasts**. Somewhat similar observations were reported in a needle aspirate by Bakhos et al (1998), and in bronchial brushing cytology by Usuda et al (1990). In the bronchial wash specimen from a case presenting as an endobronchial polyp, Devouassoux-Shisheboran et al (2004) reported numerous clusters and sheets of small to medium, mononuclear cells with round or oval nuclei, dispersed chromatin, inconspicuous nucleoli, and scanty cyanophilic cytoplasm. Numerous foamy macrophages were also present.

Follicular (Lymphocytic) Bronchitis

Follicular bronchitis is uncommon and of unknown etiology, but presumably reflects a chronic inflammatory process. It is characterized by **lymphoid deposits in the submucosa of the bronchi**, similar to follicular cervicitis.

Bronchial brushing may remove fragments of lymphoid tissue, and the resulting smear shows **dense aggregates of lymphocytes of varying degrees of maturity** (see Fig. 19-11D). Mitotic figures may be observed among follicle center cells. Similar clusters of lymphocytes may be dislodged from tonsillar tissue, and it may be difficult to exclude this possibility. The cytologic presentation is essentially that of follicular cervicitis (see Chap. 10). The **differential diagnosis** comprises **small (oat) cell carcinoma, lymphoma and leukemia**, none of which forms equally dense aggregates of lymphoid cells in a mixed pattern of immature and mature lymphocytic cells.

P.627

THERMAL INJURY

Acute Thermal Injury

The effects of inhaling hot gases and smoke have been studied by Ambiavagar et al (1974) in burn victims. In severely burned patients, there was extensive necrosis (“burning”) of cells. The **mucus** aspirated from the respiratory tract of such patients was **thick**. There was **marked**

destruction of ciliated cells. In less severely burned patients, the abnormalities were less marked, and normal ciliated cells were present next to injured cells. **The degree of cytologic damage correlated well with prognosis;** patients with severe cellular damage either died or survived only with the greatest difficulty. Patients with relatively slight damage recovered. **Mitochondrial calcification** was noted in ciliated cells of burn patients by electron microscopy (Drut, 1998).

Cooney et al (1972) reported abnormal squamous cells in the sputum of 36 burn patients admitted to a burn center. The cells were enlarged, polygonal, oval, or spindly, often multinucleated and provided with hyperchromatic nuclei. They probably represented atypical squamous metaplasia of bronchial lining. Evidence of **viral pneumonitis** (herpes and cytomegalovirus) and **moniliasis** were seen in five of those patients.

Chronic Thermal Injury

Ambiavagar et al (1974) followed a few burn patients by repeated cytologic sampling from the respiratory tract and reported an increase of squamous cells in specimens aspirated from the trachea and bronchi as the patients recovered. They suggested that **squamous metaplasia was taking place** in the injured tracheobronchial tree. We observed **atypical squamous metaplasia of bronchial mucosa in sputum and bronchial brush specimens from firemen exposed to smoke inhalation;** the lesion was reversible.

TREATMENT EFFECTS

Certain forms of therapy, especially radiation and cancer chemotherapy, may cause significant changes within the respiratory tract as in tissues of other organs, notably in the uterine cervix and urinary bladder (see Chaps. 18 and 22). The abnormalities of bronchial cells and pneumocytes type II observed after radiotherapy are similar to irradiation-induced atypias in other cell types. Both the squamous and respiratory epithelia may be greatly affected, and they may produce cells so abnormal as to suggest the presence of a malignant tumor.

Radiation Therapy

Squamous Epithelium

Acute radiation changes may be observed in squamous cells in sputum for several weeks or months after completion of irradiation and care must be taken that they not be mistaken for residual squamous carcinoma. Much of this is due to the effect of irradiation on oropharyngeal epithelium, but metaplastic squamous mucosa of the tracheobronchial tree also may be affected. Radiation atypia has been observed not only as a result of direct irradiation, but also when the target of therapy is in the neck or thorax. The mechanism is unknown but likely due to scattering of the radiant energy from nearby target tissues (abscopal effect). Minimal cellular changes may persist for months or years after the acute effects regress.

Cytology

The radiation changes induced in squamous epithelium are not unlike those seen in the female genital tract (see Chap. 18). Of these, **marked cellular enlargement** associated with proportionate enlargement of the nucleus is of prime interest, because it may be mistaken for cancer. **The enlarged nuclei of huge irradiated squamous cells are often wrinkled or wavy, and have a peculiar “empty” look with very finely granular chromatin** (Fig. 19-57A). Other changes include **multinucleation, prominent nucleoli** (Fig. 19-57B), and **nuclear or cytoplasmic vacuolization. Nuclear hyperchromasia with cytoplasmic keratinization may be indistinguishable from squamous carcinoma.** Figure 19-57C shows

irradiation atypia simulating a squamous cancer pearl in sputum of a 20-year-old man following irradiation to the chest for metastatic choriocarcinoma.

Chronic radiation effects may be seen for many months after completion of treatment. The squamous cells show slight irregularity and mild hyperchromasia of nuclei, and cytoplasmic eosinophilia (Fig. 19-57D). The diagnosis is made only with knowledge of the history of prior irradiation.

Respiratory Epithelium

The acute effects of irradiation on respiratory epithelium may occasionally result in **nonspecific multinucleation of ciliated bronchial cells** described earlier (see Fig. 19-19A,B). **However, the most characteristic effect, strongly suggestive of irradiation, is marked enlargement of all cellular components with preservation of the nucleocytoplasmic ratio. These otherwise well-formed large bronchial cells have prominent nuclei, and either enlarged nucleoli or several large chromatin granules** (Fig. 19-58A).

Multinucleation and intranuclear cytoplasmic inclusions or nuclear holes in the enlarged cells are very suggestive of irradiation effect (Fig. 19-58B). In extreme cases, **bizarre cellular forms** with cellular and nuclear enlargement may far exceed what is usually seen with carcinoma, and one should exercise great diagnostic caution even in the absence of a history of irradiation. In fact, **the finding of very bizarre giant cells is more commonly caused by radiation than by the uncommon giant cell carcinoma**. The history of irradiation warrants very careful search for remnants of the terminal bar or cilia, which may prevent an unwarranted diagnosis of cancer.

Chronic Radiation Injury

Radiation-induced changes in the lung parenchyma progress with time following completion of treatment, and

P.628

often appear clinically and histologically out of proportion to the irradiation administered. In histologic sections, the initial marked enlargement of bronchial epithelial cells is accompanied by bronchial metaplasia of alveoli and/or hyperplasia of pneumocytes type II with proliferation of interstitial fibroblasts and progressive interstitial fibrosis (Fig. 19-58C). The presence of a few irradiated bronchial cells may be the only evidence of pulmonary parenchymal irradiation in such cases (Fig. 19-58D).

Figure 19-57 Acute irradiation effect on squamous epithelium. *A.* Sputum specimen from a young woman with Hodgkin's disease following irradiation to the neck and mediastinum. There is marked cellular and nuclear enlargement with loss of nuclear chromatin texture. This degree of cellular and nuclear enlargement is virtually pathognomonic of acute irradiation effect. The cell may be of oral mucosal origin and presumably was irradiated by scattering of the radiation beam. *B.* Cellular enlargement, multinucleation, nuclear vacuolization, and prominent chromocenters or nucleoli. *C.* Sputum specimen from a 20-year-old patient after irradiation to the lung for metastatic choriocarcinoma. This keratinized squamous pearl is indistinguishable from squamous carcinoma. *D. Late irradiation effect on squamous epithelium:* The cytologic pattern is nonspecific, and interpretation is based on clinical correlation with the known history of prior irradiation. There is cytoplasmic eosinophilia and slight nuclear enlargement with hyperchromasia. Note the strong similarity to radiation-induced atrophy and atypia in cervicovaginal smears. (*C:* oil immersion.)

With the passage of time, there is **progressive diffuse interstitial pulmonary fibrosis** associated with metaplastic changes within the alveolar and bronchial lining epithelia. Enlargement of **pneumocytes type II** and **squamous metaplasia** are the dominant epithelial abnormalities.

Cytology

The late irradiation effects in sputum and bronchial brush specimens vary from minimal nonspecific atypias and squamous metaplasia, as is often seen in the absence of irradiation (see Fig. 19-23), to **less common extreme degrees of atypical squamous metaplasia**. In this latter instance, **the cells of bronchial origin may show marked cytoplasmic eosinophilia, distortion of cell shapes, and nuclear hyperchromasia or pyknosis, combining to create a cytologic image mimicking epidermoid cancer**. The exfoliated cells are sometimes arranged in strips, consistent with origin in the bronchial epithelium.

Carcinoma Versus Radiation Effect

From time to time, the cytopathologist may be called upon to **determine whether or not there is residual viable carcinoma in patients undergoing irradiation for lung cancer**. **Acute radiation pneumonitis** is accompanied by pulmonary edema, desquamation of a great many **degenerated bronchoalveolar epithelial cells**, much necrosis, strands of smeared nuclear material, and an accumulation of leukocytes. In this material, it is nearly impossible to exclude the

P.629

presence of rare cancer cells. Equally difficult in some cases, as noted above, is the differential diagnosis between marked radiation-induced atypical metaplasia and cancer, particularly when recurrence of irradiated squamous carcinoma is anticipated. **A good rule is to not make the diagnosis of cancer unless cancer cells not affected by irradiation are clearly identified at least 6 weeks after completing treatment**. That is usually the case if there is viable residual or recurrent carcinoma. The history of radiation should caution against the cytologic diagnosis of cancer on less-than-certain evidence.

Figure 19-58 Acute irradiation effect on bronchial epithelium. *A.* Marked enlargement of bronchial cell with proportional enlargement of nucleus after 6,000 rad irradiation. *B.* Cellular enlargement, multinucleation, nuclear vacuolization and loss of chromatin structure. Cilia may be retained (oil immersion). **Late irradiation effect on lung.** *C.* Interstitial fibrosis is a late effect of irradiation, with hypertrophic alveolar epithelium and prominent nuclei in alveolar and stromal cells. *D.* Marked nuclear enlargement and hyperchromatic in a patient treated for lung cancer.

Chemotherapy

Chemotherapy-induced histologic abnormalities of the bronchial epithelium were first reported by Weston and Guin in 1955, in children undergoing leukemia treatment. They observed nuclear abnormalities such as enlargement and hyperchromasia in normal epithelia. Similar histologic abnormalities have been noted in adult patients receiving chemotherapy, especially alkylating agents.

Busulfan

Busulfan (Myleran), an alkylating agent used for treating chronic myelogenous leukemia, is discussed in Chapter 18. It is capable of inducing severe alterations in bronchial and alveolar epithelium, and in interstitial tissues of the lung (for summary of pertinent early literature, see Koss et al, 1965; Feingold and Koss, 1969). The pulmonary abnormalities received the name of **busulfan lung** (Heard and Cooke, 1968). Clinically, these patients are dyspneic because of **interstitial pulmonary fibrosis** that radiologically may mimic diffuse, lymphangitic spread of carcinoma.

Very large cells with correspondingly large, hyperchromatic or sometimes vesicular nuclei are seen in histologic sections of the bronchial epithelium (Fig. 19-59A), bronchioles and alveoli (Fig. 19-59B), and are found in sputum (Figs. 19-59C) and bronchial brush (Fig. 19-59D) specimens. The most severely damaged, abnormal cells are pneumocytes type II.

In the case of busulfan-induced atypias of the respiratory tract, as with drug-induced changes in the uterine cervix, the differential diagnosis with cancer may present a significant challenge. There is increasing evidence, as discussed in Chapter 18, that the changes induced by some of the alkylating agents are carcinogenic.

A case is on record of bronchogenic adenocarcinoma occurring in a patient receiving long-term busulfan therapy (Min and Gyorkey, 1968). Another such case seen by one

P.630

of us (LGK) was that of a 69-year-old man with chronic myelogenous leukemia who had been receiving busulfan therapy (4 mg/day) for 2½ years. He developed severe dyspnea, suggestive of acute busulfan lung. His sputum contained a moderate number of abnormal squamous cells suggestive of busulfan effect and other cells that were highly suggestive of carcinoma. This patient's chest radiograph showed only diffuse fibrosis with no localizing lesion, and he was not treated. At autopsy, a small, poorly differentiated squamous carcinoma was found in a busulfan lung. It should be noted that **busulfan is often administered to patients prior to bone marrow transplant** and may account for cellular abnormalities seen in some of those patients. Other changes caused by busulfan are described in Chapters 18 and 22.

Figure 19-59 Busulfan (Myleran) treatment effect. *A.* Drug-induced atypia of bronchial epithelium in a patient treated for chronic myelogenous leukemia. The epithelium is disorderly, nuclei are enlarged and vesicular or hyperchromatic. *B.* Atypia of bronchiolar epithelium. Busulfan-induced atypia mimicking carcinoma in sputum (*C1, C2*) and bronchial brushing (*D*).

Bleomycin

Bleomycin, an antibiotic with antineoplastic properties, has been used for several years in treating testicular tumors and squamous carcinomas of various organs. The drug induces **keratinization and death of squamous cancer cells**, which in turn, induces formation of **multinucleated macrophages that phagocytize keratin** (Burkhardt et al, 1976). The principal effect of the drug on the lung is the development of an interstitial pneumonia and interstitial fibrosis (Luna et al, 1972) that is **similar to busulfan lung except that cellular**

abnormalities are minimal (Fig. 19-60A). Extensive squamous metaplasia of the bronchial lining is observed on occasion, and significant cytologic atypia has been observed when bleomycin is used in conjunction with other drugs in combination chemotherapy (Fig. 19-60B).

P.631

Of interest, the interstitial fibrosis of Hamman-Rich syndrome also was associated with epithelial atypias in a report by Kern (1965) who classified cells as “suspicious” in 2 of 11 such patients.

Figure 19-60 Bleomycin effect. *A*. Bleomycin treatment of lymphoma resulted in interstitial pulmonary fibrosis with only minimal alveolar epithelial hyperplasia. *B*. In combination with Chloromycetin, Bleomycin caused marked atypia of bronchial epithelium in a brush specimen.

Cyclophosphamide

Cyclophosphamide (Cytoxan), an alkylating agent widely used in treatment of neoplastic disease, is noted primarily for its effect on urothelium of the bladder (see Chap. 22). It may cause significant atypias of bronchial and alveolar epithelium as well. Figure 19-61A shows metaplasia and atypia of bronchoalveolar epithelium attributed to cyclophosphamide treatment in a woman with breast cancer. Bronchial cell atypia in a bronchial brush specimen of another patient receiving Cytoxan is shown in Figure 19-61B,C.

We observed diffuse pulmonary fibrosis in a patient receiving **cyclophosphamide** in large doses for 3 years. Several additional cases of this type have been recorded, summarized in early reports by Patel et al (1976) and Mark et al (1978).

A case report of pulmonary fibrosis and busulfan-like syndrome caused by **chlorambucil** (Leukeran) was described by Rose (1975). Cole et al (1978) reported alveolar lining cell dysplasia as well as interstitial pulmonary fibrosis in a patient who was treated with chlorambucil for polycythemia vera. Wada et al (1968) observed a statistically **significant increase in lung cancer among workers engaged in the manufacture of mustard gas**, which is closely related to nitrogen mustard, the prototype of all chemotherapeutic alkylating agents including cyclophosphamide and chlorambucil.

Methotrexate

This drug acts by inhibition of the enzyme folic acid reductase and is extensively used in the treatment of various neoplastic diseases including **choriocarcinoma** and **certain leukemias**. It has also been used in the treatment of patients with **psoriasis, rheumatoid arthritis**, and other benign disorders. The drug causes liver abnormalities and occasionally pulmonary

complications (Clarysse et al, 1969) in the form of **interstitial pneumonias** and apparently **granulomas** (Filip et al, 1971). Van der Veen et al (1995) described two **fatal cases of pulmonary fibrosis** in aged patients after low-dose methotrexate therapy for rheumatoid arthritis. Postmortem examination disclosed extensive pulmonary fibrosis, obliterative bronchiolitis and hyperplasia of type II pneumocytes. There are no known cytologic studies of these patients.

Carmustine (bis-Chloroethylnitrosourea [BCNU])

Nitrosoureas are a group of anticancer chemotherapeutic agents used extensively in the therapy of many malignant tumors including leukemias, lymphomas, melanomas, Ewing's tumor, various carcinomas, and brain tumors. Fatal interstitial pulmonary fibrosis has been reported by Holoye et al (1976).

One of our patients who died apparently as a **consequence of chemotherapy for a brain tumor had cytologic abnormalities in what we now believe to be reactive type II pneumocytes that were a perfect mimic of adenocarcinoma** (Fig. 19-62 A,B), **including cells in mitosis** (Fig. 19-62C). The patient, whose death was attributed to viral pneumonia, had been treated with the chemotherapeutic drug, carmustine (BCNU). At autopsy, there was no evidence of tumor in the lung. There was interstitial pulmonary fibrosis and cell gigantism (Fig. 19-62D) that was first thought to represent drug effect but later attributed to viral pneumonia. It was probably due to the combined effect of the chemotherapeutic drug and viral infection. Additional

P.632

experience is still required to ascertain the precise effects of this drug on the cytology of the lung.

Figure 19-61 Cyclophosphamide (Cytoxan) effect. A. Histologic section of lung from a woman who had been receiving cyclophosphamide treatment for breast cancer and developed respiratory symptoms. There was atypical bronchial metaplasia of terminal bronchioles and alveolar epithelium. She did not have lung metastases. B,C. Bronchial brush cytology specimens from another patient on long-term cyclophosphamide treatment showing nuclear enlargement with prominent chromocenters and small nucleoli in bronchial cells.

Combination Chemotherapy

Single-drug chemotherapy is now the exception rather than the rule, increasing the likelihood of drug-induced cytologic atypias. Examples of bronchial cell abnormalities in a BAL specimen from a 22-year-old man on multidrug therapy for acute lymphocytic leukemia is illustrated in Figure 19-63A,B, and in squamous cells in sputum from another patient with Hodgkin's disease in Figure 19-63C. Bronchial epithelial atypia in a child on multidrug therapy for leukemia is shown in Figure 19-63 D. Complete and accurate clinical information is increasingly important in the interpretation of cytologic specimens.

Amiodarone

Amiodarone is representative of a new class of very potent antiarrhythmic drugs used to treat cardiac arrhythmias. The drug, taken over a number of years in large doses, may cause a **variety of toxic effects** involving a number of organs such as the skin, thyroid, liver, bone marrow, and others. In a certain proportion of patients, **lung lesions** may develop. The frequency of lung disease has been significantly reduced with lower doses of the drug, averaging 200 mg daily.

The **clinical manifestations** of pulmonary toxicity include **progressive dyspnea and cough**. A pleural effusion may occasionally be observed (Stein et al, 1987). Roentgenologic findings are **bilateral pulmonary infiltrates**, initially affecting mainly the lower lung lobes. **The basic injury from the drug appears to be an accumulation of phospholipids in the cytoplasm of macrophages**. The appearance has suggested a **drug-induced storage disease**. **Large mono- and multinucleated macrophages with finely vacuolated, foamy cytoplasm are characteristic of this disorder and have been described in BAL or in pleural fluid** (Martin et al, 1985; Stein et al, 1987; Mermolja et al, 1994; Bedrossian et al, 1997) (Fig.19-64). Stein et al (1987) stressed the **similarity of the foamy macrophages to cells in lipid pneumonia**. Osmiophilic lamellar inclusion bodies were observed in lysosomes by electron microscopy (Colgan et al, 1984; Dake et al, 1985), corresponding to foamy inclusions in alveolar macrophages by light microscopy (Israel-Biet et al, 1987; Myers et al, 1987; Bedrossian et al, 1997). **Reactive hyperplasia and damage to type II pneumocytes, a massive accumulation of large alveolar macrophages, and interstitial fibrosis** have been reported (Colgan et al, 1984).

Amiodarone lung must be differentiated from other disorders with similar clinical and roentgenologic presentation; the diagnosis requires correlation of clinical and roentgenologic data. Because **BAL** is safer than open lung biopsy for seriously ill patients, it is the **preferred diagnostic procedure**

P.633

to identify abnormal macrophages. Whether induced sputum may be equally effective has not been tested.

Figure 19-62 BCNU. Probable effects of carmustine (bis-chloroethylnitrosourea, BCNU) and viral pneumonia. Bronchopulmonary cytology and lung tissue at autopsy of a 29-year-old man with an astrocytoma treated by irradiation to the brain and systemic chemotherapy with BCNU. The patient died of respiratory failure after a febrile illness of 2 weeks' duration. *A.* Round papillary cluster of cells with prominent nucleoli. *B.* A single, very large cell with prominent nucleolus. *C.* Cell in telophase of mitosis. *D.* Autopsy sections of lung showed interstitial fibrosis and scattered cells with giant nuclei, probably a drug effect. Alveoli were lined by prominent type II pneumocytes, and in this illustration, a syncytium of desquamated atypical pneumocytes with prominent nucleoli are seen within an alveolus.

Organ Transplantation

Bone Marrow Transplantation

Autologous and allogeneic bone marrow transplants are used to **protect the hematopoietic system of the patient from the effects of high-dose chemotherapy and sometimes total body irradiation**. This approach is used in the treatment of **patients with systemic cancer**, most commonly patients with lymphoma, leukemia and, until recently, for metastatic breast cancer. The transplant recipients are **severely immunosuppressed** by their drug treatment and are **susceptible to opportunistic infections**. Lobenthal and Hajdu (1990) described their findings in various cytologic specimens that included cerebrospinal fluid and respiratory tract samples from 328 patients receiving bone marrow transplants, mainly for treatment of leukemias. Sputum, bronchial washing and **BAL** specimens of 92 patients were examined. Their principal observations were **marked enlargement and nuclear hyperchromasia** of epithelial cells, presumably pneumocytes type II, attributed to total body irradiation. In several patients, *P. carinii* and **cytomegalovirus infections** were observed. The investigators were not successful in predicting recurrent leukemia in these patients based on cytologic changes.

Abu-Farsakh et al (1995) studied the **BAL specimens** from 77 recipients of bone marrow transplants who developed pulmonary symptoms or lung infiltrates on chest x-ray. The purpose of the study was to determine whether cytologic findings in BAL were of prognostic value. Bizarre epithelial cell changes were observed in specimens from 14 patients, some of which affected pneumocytes type II. These cells had markedly enlarged, hyperchromatic nuclei that were similar to the nuclear changes observed in atypical pneumonias, interstitial pulmonary fibrosis, or busulfan lung (see above). Also of note was the presence of 36 nonbacterial

infections, 14 caused by fungi, mainly *Aspergillus*, and 19 that were viral (14 with **cytomegalovirus** and 5 with **herpes simplex**). In this series, there were three statistically significant **indicators of a poor prognosis**: (1) low lymphocyte counts (<5/hpf); (2) presence of hemosiderin laden macrophages; and (3) opportunistic viral or fungal infections.

P.634

Figure 19-63 Atypia induced by combination chemotherapy. *A,B.* BAL cytology from a 22-year-old man under treatment for acute lymphocytic leukemia, showing enlarged and atypical columnar cells (*A*) and goblet cells (*B*). *C.* Squamous pearl perfectly mimicking squamous carcinoma in bronchial irrigation cytology of a young woman with Hodgkin's disease. She was treated with Velban, Leukeran, and radiotherapy. *D.* Chemotherapy-induced bronchial epithelial atypia in a child with acute leukemia. (*A-C*: High magnification.)

Lung Transplantation

Selvaggi (1992) reported her observations on six patients receiving lung transplantation. **BAL specimens** were used to **monitor the rejection of the transplanted organs**. The principal cytologic findings included **hyperplasia of pneumocytes type II** and the presence of inflammatory cells. **Cytomegalovirus** and **candida species** infections were each observed in one patient. When compared with concurrent lung biopsies, cytologic studies were a poor predictor of organ rejection.

NEONATAL LUNG DISEASE

Bronchopulmonary Dysplasia of Newborns

Northway and Rosan (1969) define **bronchopulmonary dysplasia** as a disorder of the respiratory tract occurring in neonates with respiratory distress syndrome, treated with intermittent positive-pressure respirators and high oxygen concentration for more than 6 days. The high oxygen pressure induces pulmonary injury, which can be monitored by radiographic and cytologic examination of pulmonary secretions. Northway and Rosan identified four stages of bronchopulmonary dysplasia that can be described as follows:

- **Stage I** of oxygen toxicity (1 to 3 days of age) is characterized by **bronchial epithelial**

necrosis. The chest radiograph shows fine granular densities, and the **cytologic examination of aspirated secretions shows excessive shedding of normal bronchial cells.**

- **Stage II** (4 to 10 days of age) is characterized by **nearly complete opacification of both lungs.** **Cytologic examination** shows **loss of ciliated respiratory cells.** **Abnormal, bizarre cell forms** appear toward the end of this stage, indicating progressive necrosis and the beginning of epithelial regeneration. This stage of disease still responds favorably to withdrawn or reduced oxygen therapy.
- **Stage III** (10 to 20 days of age) is a period of **cellular atypia and transition** to chronic disease. Radiographic examination shows areas of radiolucency in the previously completely opacified lungs. **Cytologic specimens** show **squamous metaplasia** and **mitotic activity** suggestive of healing of the denuded epithelial areas (D'Ablang et al, 1975). There is an increase in thick and viscid mucus secretions.

P.635

- **Stage IV** represents **irreparable, chronic lung disease.** The **cytologic findings** in this stage of the disease show **progressive squamous metaplasia** and atypia, probably of pneumocytes type II. At autopsy, the lungs show squamous metaplasia of bronchial lining, marked interstitial fibrosis, and emphysema. D'Ablang et al confirmed the above findings in a major study, and suggested that careful monitoring by x-ray examination and **cytology could identify the high-risk infants** (Fig. 19-65).

Figure 19-64 Amiodarone lung, BAL. *A.* The presence of numerous alveolar macrophages with abundant vacuolated cytoplasm characterizes this disorder (high magnification). *B.* Higher-power magnification of the macrophages, some of which are binucleated (*inset*). Note the unusual configuration of the vacuolated cytoplasm. A single bronchial cell in the field also shows a cytoplasmic vacuole. *C.* Electron micrograph of one of the lavaged macrophages showing very numerous cytoplasmic lamellar inclusions, resembling fingerprints, reflecting accumulation of lipids. (Courtesy of Dr. G. S. Zaatari, Dallas, TX. From Stein B, et al. Amiodarone pulmonary toxicity: clinical, cytologic, and ultrastructural findings. *Acta Cytol* 31:357-361, 1987.) (*B*: oil immersion; *C*: $\times 11,000$.)

Other Pulmonary Disorders in Neonates

Doshi et al (1982) reported on the value of tracheal aspiration cytology in a number of pulmonary disorders other

P.636

than bronchopulmonary dysplasia. Thus, **hyaline membrane disease**, **pneumonia**, **amniotic fluid**, **meconium aspiration**, and **pulmonary hemorrhage** were described. Of note was the finding of **massive desquamation of bronchial cells**, **ciliocytophthoria** and **fragments of hyaline membranes in hyaline membrane disease**. **Meconium aspiration** was characterized by the presence of **fragmented squames** and **coarse cellular debris**.

Anucleated squames were the dominant cytologic finding in **amniotic fluid aspiration** (see Chap. 27).

Figure 19-65 Cytologic manifestations of bronchopulmonary dysplasia of newborns in aspirated bronchial secretions. *A,B.* Stage II: respiratory columnar cells with loss of cilia (*A*); cohesive clusters of deep bronchial epithelial cells (*B*). *C,D.* Stage III: atypical cells of bronchial epithelial origin (*C*); some cells with mitotic activity (*D*). The findings correspond to regeneration of bronchial epithelial lining. *E,F.* Stages III and IV: squamous metaplasia of bronchial lining (*E*); bizarre squamous cells (*F*). These findings correspond to replacement of bronchial epithelium by atypical squamous metaplasia, evidence of irreversible pulmonary damage. (*A-F:* High magnification.) (From D'Ablaing G, et al. Neonatal pulmonary cytology and bronchopulmonary dysplasia. *Acta Cytol* 19:21-27, 1975.)

Tumors of the Lung: Conventional Cytology and Aspiration Biopsy

Myron R. Melamed

P.644

At the onset of the 21st century, cancer of the lung remains the most common cause of cancer deaths in men and women alike, as it has been for many years (Landis et al, 1999). The link between lung cancer and cigarette smoking was emphasized half a century ago by Wynder and Graham (1950) and became officially recognized in 1957 when the Surgeon General of the United States, Leroy E. Burney, issued a statement declaring, "Excessive smoking is one of the causative factors in lung cancer." This was followed by a Public Health Service Monograph, "Smoking and Health" published in 1964 (PHS monograph 1103) that exhaustively reviewed the health effects of cigarette smoking and clearly established the relationship between cigarette smoking and lung cancer. It may be assumed that a subsequent decrease in cigarette smoking accounts for the recent modest drop in the incidence and deaths from this disease in the US. The relationship between cigarette smoking and lung cancer is complex, however, and individuals differ in their susceptibility to the carcinogenic effects of cigarette smoking and probably other environmental agents (Spitz, 1999); the challenge of the future will be to identify those who are constitutionally at risk.

Lung cancer is also an occupational disease. The earliest recorded cases of occupational lung cancer, first recognized in 1879, were among the Schneeberg and Joachimstal miners of Czechoslovakia who were exposed to radon gas in material known as *Pitchblende*, from which Pierre and Marie Curie extracted and isolated radium. In the US, lung cancer in Colorado uranium miners has been attributed to radiation (Archer et al, 1974; Saccomanno et al, 1988). Arsenic, long known to produce cutaneous hyperkeratoses, is now also recognized as a cause of lung cancer. At least 12 substances found in the workplace are considered to be lung carcinogens in humans, and 5% of lung cancers in the US have been attributed to occupational exposure (Doll and Peto, 1981). The industrial agents reported to cause lung cancer include chloromethyl ether, mustard gas, polycyclic aromatic hydrocarbons, crystalline silica, nickel, chromium, beryllium, cadmium, and asbestos, the last in association with cigarette smoking (Braun and Truant, 1958; Cordova et al, 1962; Talcott et al, 1989; Rosenman and Stanbury, 1996; Steenland et al, 1996; Beckett, 2000). Of these, asbestos is of particular interest to the cytopathologist because these fibers can be identified in specimens of sputum (see Chap. 19). Asbestos fibers may be observed in sputum simultaneously with cancer cells, as was first demonstrated by An and Koprowska in 1962. For a comprehensive review of the pathology of asbestos associated diseases, see Roggli et al, 1992.

Finally, human papillomavirus (HPV) has been implicated in the pathogenesis of squamous lung

cancer. Syrjänen et al (1989) reported finding HPV types 6 and 16 in 9 of 131 squamous lung cancers. On the other hand, Stremlau et al (1985) hybridized tissue from 24 lung tumor biopsies with 10 different HPV types and found only 1 carcinoma with HPV (type 16). The latter occurred in a woman with a history of treated cervical carcinoma and the lung tumor may have represented metastatic cancer. Thus, the evidence that **HPV has a role in carcinogenesis of the lung is unconfirmed**. See also comments on the role of HPV in cervical cancer (Chap. 11), lesions of the oral cavity and larynx (Chap. 21), and the esophagus (Chap. 24).

The relative frequency of the histologic subtypes of lung cancer in the US has changed dramatically over the last several decades (Vincent et al, 1977; Johnston, 1988; Devesa et al, 1991; Sobue et al, 1999). Squamous cancers, which were predominant in the 1950s and 1960s, now account for no more than 30% of cases. At the same time, **peripheral adenocarcinomas of the lung have increased in frequency and are now the most common type of lung cancer in the US**. The reason for this is unknown but has been attributed to changes in the manufacture of cigarettes, the use of filter tips, or the possible effects of other environmental cofactors. As a result, **sputum cytology, which best detects early squamous carcinomas, is less useful as a screening tool now than in prior years**. On the other hand, **percutaneous aspiration of peripheral lung lesions has become increasingly important in early diagnosis of small peripheral carcinomas**, even as tiny as 2 to 5 mm, and may prove of value in assessing lesions found by high-resolution spiral or helical computed tomography (CT) (Henschke et al, 1999).

Surgery remains the treatment of choice for all but small-cell lung cancer; even with recent advances in chemotherapy and radiotherapy, the **best opportunity for long-term survival and cure of lung cancer lies in early diagnosis and surgical resection**. A major feasibility study of early lung cancer detection, encompassing over 30,000 cigarette-smoking men who were followed for 5 to 8 years (Berlin et al, 1984; Flehinger et al, 1984; Fontana et al, 1984; Frost et al, 1984) has now been concluded (Melamed et al, 1984; Melamed and Flehinger, 1987; Flehinger et al, 1988; Melamed, 2000) and is summarized below. The results of this study failed to show a decrease in death rates from lung cancer, leading the **American Cancer Society and other influential agencies to recommend against screening for lung cancer**. **Chest x-rays and sputum cytology were considered to be diagnostic tools for symptomatic patients only. Because symptomatic lung cancer is usually advanced lung cancer, however, the opportunity for early diagnosis and cure is lost**. In a recent evaluation of the statistical basis for this recommendation, Dempster (1998) concluded that **the study data “strongly support a finding**

P.645

of benefit from routine screening of high-risk populations.” Flehinger and Kimmel (1987) have estimated that annual radiographic screening alone would decrease mortality from adenocarcinoma of the lung by up to 18%. The results of extensive Japanese lung cancer studies also suggest that surgical removal of very small adenocarcinomas, discovered by the new methods of CT, can improve the cure rate significantly (Noguchi et al, 1995).

Ongoing studies of lung cancer detection, using **spiral CT** (spiral or helical CT), known as the Early Lung Cancer Action Project (**ELCAP**), summarized later in this chapter, may yet modify future recommendations regarding screening for lung cancer (Henschke, 2000). This project, if successful, is likely to pose new challenges for interpretation of cytology of sputum, bronchial brushes, bronchoalveolar lavage, and particularly transbronchial and percutaneous needle aspirates.

It must be emphasized that **cytology is a method of choice in the diagnosis of radiologically detected lung lesions suspected of being malignant**. Thus, it is appropriate to analyze briefly the existing methods of diagnosis of lung cancer with attention to the role of cytology.

METHODS OF DIAGNOSIS OF LUNG CANCER

Asymptomatic Population

The original approach to the detection and diagnosis of early lung cancer in asymptomatic, high-risk individuals was based on an examination of conventional chest roentgenograms and sputum cytology. At present, spontaneously produced or artificially induced sputum only rarely leads to the discovery of an occult lung cancer (see below). Most early (small) lung cancers in asymptomatic individuals are incidental findings on routine chest roentgenograms, and increasingly sophisticated imaging techniques such as spiral CT are now proposed to screen for the very earliest, potentially curable cancers. Whether these techniques will lead to earlier diagnosis and more successful treatment of lung cancer is the subject of ongoing studies.

Symptomatic Population

Roentgenologic Techniques

For patients with symptoms of cough, hemoptysis or chest pain and radiologic abnormalities, whether or not suggestive of lung cancer, there are several avenues of further investigation. Conventional and high-resolution CT may help clarify the nature of a suspicious lesion or narrow the diagnostic possibilities. More specific diagnosis requires morphologic examination and analysis by cytologic techniques or by biopsy.

Cytologic Techniques

Cytologic examination of sputum, bronchial secretions, and aspirates has a dual purpose:

- **To determine the presence of tumor**
- **To classify the tumor as accurately as possible according to predominant histologic type.** This task is of considerable importance, since it may influence the mode of treatment in individual cases. The **identification of small-cell carcinoma (SSC) versus all other (non-SSC) types is of primary importance.**

In competent hands and with experience, cytologic procedures serve to render the diagnosis of lung cancer with precision, speed, and accuracy equal to or even superior to other techniques. The benefits of cytologic methods are substantial, as they often offer the option of treatment planning without the need for an open biopsy. It should be emphasized, however, that **the interpretation of cytologic findings must always be made in the context of clinical findings**, since certain benign processes can induce cellular changes that mimic a malignant neoplasm (see Chap. 19).

Sputum

Sputum cytology is the oldest and simplest of these diagnostic procedures and is readily available to every medical practitioner (summary in Wandall, 1944). **It can provide a diagnosis in about 80% of primary lung carcinomas**, depending on tumor type and stage. As already noted, cytology of sputum is most effective in the diagnosis of squamous carcinomas of the

lung, although other types of cancer can be recognized and diagnosed as well. Sputum cytology also may provide a substrate to **search for diagnostic molecular markers of lung cancer** (Tockman et al, 1997; Ahrendt et al, 1999).

Bronchial Brushings and Washings

Samples obtained by the fiberoptic bronchoscope also are very effective in the diagnosis and differential diagnosis of cancer. Brush specimens, obtained directly from the suspect lesion, often provide an **excellent sample and exact information on the location of the disease**. The rigid bronchoscope, now seldom used, limits examination to the mainstem, lobar, and lower lobe segmental bronchi.

Bronchoalveolar Lavage (BAL)

This technique was discussed in detail in Chapter 19. With increasing incidence of peripheral adenocarcinomas, **BAL has begun to play a more important role in the diagnosis of lung cancer**. Initial reports of lung cancer diagnosed by BAL (Springmeyer et al, 1983; Lindner et al, 1987) were supported by a recent study in which BAL was positive for malignant cells in 14 of 30 patients with endoscopically invisible tumors, whereas transbronchial biopsy was positive in only 5 of those patients (Wongsurakiat et al, 1998). **The technique was also very effective in the diagnosis of lymphangitic carcinomatosis caused by metastatic cancer (Levy et al, 1988)**, but not as useful for other metastatic cancer. As ever-smaller lesions of the lung are detected by spiral CT, whether used as a diagnostic or screening tool, BAL will come under further evaluation (Sone et al, 1998; Henschke et al, 1999). **BAL specimens may also be used for molecular analyses in the search for diagnostic or prognostic markers** (Tockman, 2000).

P.646

Percutaneous Fine-Needle Aspiration Biopsy (FNA)

This method, performed under radiologic guidance, was described in Chapter 19, with a discussion of potential complications. It has been recognized since the 1970s as a critically important diagnostic technique (Koss et al, 1992), and is particularly valuable in the diagnosis of space-occupying lesions located in the periphery of the lung and in the mediastinum. The technique is used with increasing frequency to investigate pulmonary infiltrates as well as more discrete masses in the lung.

Transbronchial FNA Biopsy

Transbronchial FNA biopsy (TBFNA) is performed during fiberoptic bronchoscopy for diagnosis of tumor masses located outside the bronchial lumen. In early reviews of this procedure (Schenk et al, 1987; Gay et al, 1989), the method was found to be useful in selected cases of primary and metastatic cancer. It is also of potential value in the recognition and diagnosis of inflammatory disease and certain benign mediastinal or parabronchial masses.

Cell Block Technique

Given an adequate specimen, a selected portion of the sputum, bronchial brush specimen or needle aspirate may be fixed, embedded in paraffin and processed by histologic techniques to supplement the cytologic examination. **Cell block sections provide the advantage of a microbiopsy, and are highly recommended for examination of any specimen in which tiny tissue fragments are present or if there is residual material after the smears have**

been prepared. It is not recommended as a substitute for the cytologic technique. Cell block sections are particularly useful if immunostains or other special stains are required.

CT-Guided Core Biopsies

This method utilizes an automatic gun provided with an 18- or 20-gauge cutting needle to obtain core biopsies of lung lesions. The method has been applied with a success rate which depends on the size of the lesions (Haramati, 1995; Arakawa et al, 1996; Laurent et al, 2000). Thus, Tsukada et al (2000) recorded a diagnostic accuracy of about 66% for lesions 6 to 10 mm in diameter, 79% for lesions 11 to 20 mm in diameter, 87% for lesions 21 to 30 mm in diameter, and 93% for larger lesions. Connor et al (2000) reported on a comparison of fluoroscopic or CT-guided core biopsies with FNA on 103 patients. These investigators concluded that **the core biopsy was superior to FNA for the diagnosis of benign lesions and superior to FNA in establishing tumor type in cancer.** The reported rate of complications, mainly pneumothorax (about 30%) and hemoptysis (1% to 2%), was comparable for both methods, with about 3% of patients requiring treatment for pneumothorax.

Haramati (personal communication, July 11, 2001) now utilizes the guided core biopsies for presumed benign lesions and FNA for presumed malignant lesions, with excellent results. It is likely that core biopsies of lung lesions will be carried out more frequently in the future, as interventional radiologists become increasingly skilled with this technique. The cytopathologist will be called upon to evaluate these specimens.

CLASSIFICATION OF LUNG CANCER

Most lung cancers are derived from the epithelium of the bronchi and bronchioles, although some tumors may originate in epithelial cells lining the alveoli. The term **bronchogenic carcinomas** is commonly used to describe these tumors. They may be classified into the following **main groups**:

- Carcinomas exhibiting predominantly squamous differentiation, classified as **squamous or epidermoid carcinomas.**
- Carcinomas forming glandular patterns, **mimicking bronchi or alveoli, classified as bronchogenic adenocarcinomas of various types or as bronchioloalveolar carcinomas.**
- Carcinomas composed of undifferentiated small cells, resembling the **basal or reserve cells of the bronchial epithelium**, forming the group of **small cell carcinomas** or **SSCs.**
- Carcinomas **composed of undifferentiated or poorly differentiated large cells, some of which may exhibit glandular or squamous differentiation, or even endocrine features.**
- **Rare types of carcinomas, including tumors with endocrine features.**

Carcinomas of lung may have **mixed histologic patterns**, in which case minor components are disregarded and the carcinoma is classified by the predominant pattern; if there are two different major components, the tumor is classified as a mixed-pattern carcinoma.

Most important from the clinical point of view is an accurate cytologic diagnosis of SCC and its differentiation from all other (non-small-cell) carcinomas. SCC is highly responsive to irradiation and chemotherapy, which is the treatment of choice, whereas all other malignant lung tumors (except for malignant lymphomas) are best treated by

surgery.

Malignant lymphomas, soft-part sarcomas, metastatic tumors and other less-common pulmonary neoplasms will be described separately. **Benign tumors** and **tumors of low malignant potential**, will be discussed in the closing pages of this chapter.

As a basis for the discussion of cytologic findings, the classification of bronchogenic carcinomas shown in Table 20-1 has been adopted here. It should be emphasized that this classification is not rigid and that transitions between and among the various types of bronchogenic carcinoma may be observed. In a thorough analysis of histologic types of 234 cases of lung cancer, Reid and Carr (1961) emphasized that only 37% of these tumors were homogeneous and the remainder were mixed, although they often showed a single dominant pattern. Roggli et al (1985) also found variations in the histologic pattern in two thirds of lung cancers, and in 45% there was more than one major histologic classification. This has been our experience also, and

P.647

it has considerable bearing on the cytologic diagnosis of tumor types in sputum and bronchial material.

TABLE 20-1 CLASSIFICATION OF PRIMARY LUNG CARCINOMAS AND RELATED TUMORS

Squamous carcinoma
Keratinizing (well-differentiated)
Poorly differentiated (epidermoid)
Large-cell undifferentiated carcinoma *
Small-cell undifferentiated carcinoma (SCC)
Oat cell carcinoma
Intermediate cell type
Adenocarcinoma
Adenocarcinoma of central bronchial origin
“Acinar” carcinoma
Solid carcinoma with mucin formation
Papillary carcinoma

Bronchioloalveolar carcinoma

Adenosquamous carcinoma

Mucoepidermoid carcinoma

Spindle and giant-cell carcinoma

Neuroendocrine tumors

Carcinoid

Atypical carcinoid (well-differentiated neuroendocrine carcinoma)

Large-cell carcinoma with endocrine differentiation

Rare carcinomas

Although a more detailed classification was recently proposed for the World Health Organization by an expert pathology panel of the International Association for the study of Lung Cancer (Travis et al, 1999), the simple classification shown here is adequate for our purpose.

* Most of these are undifferentiated large-cell adenocarcinomas, undifferentiated squamous carcinomas, or a mixture of both.

STAGING OF PRIMARY LUNG CANCER

The *TNM* system, which is based on characteristics of the primary *tumor*, lymph *nodes*, and presence of *metastases*, was devised by the American Joint Committee on Cancer (AJCC, 1997). It is widely used to classify invasive lung carcinomas into five stages, and is of value for prognosis and as a guide to therapy.

- **Occult carcinoma:** Tumor proven by cytologic diagnosis but not visualized by radiologic imaging or bronchoscopy, and location not found
- **Stage 0:** Squamous carcinoma in situ, and microinvasive carcinoma
- **Stage IA:** Carcinoma confined to the lung, no more than 3 cm in diameter
- **Stage IB:** Carcinoma confined to the lung, greater than 3 cm in diameter
- **Stage II:** Carcinoma with metastases to peribronchial or hilar lymph nodes or invading tissue adjacent to lung
- **Stage III:** Carcinoma with metastases to mediastinal lymph nodes
- **Stage IV:** Carcinoma with distant metastases

Surgically resectable stage IA carcinomas have a 5-year survival rate of about 70% (Melamed and Flehinger, 1987; Melamed et al, 1981; Flehinger et al, 1992; Melamed, 2000). Stage II carcinomas have a 5-year survival rate of about 30% (Beahrs, 1992). In stage III tumors, the survival rate is 10% at 5 years, and in stage IV tumors, it is almost anecdotal (Beahrs, 1992; AJCC, 1997). All SSCs are stage IV by definition.

The optimal goal of cytology is to detect lung cancer in the earliest possible stage, ideally at stage T0, which defines initially occult carcinomas diagnosed by cytology in the absence of roentgenologic abnormalities, or stage 1A, which comprises localized carcinomas smaller than 3 cm in diameter without evidence of metastases. As already noted, these two groups of early-stage carcinomas offer significantly better prognosis than the more advanced tumors in stages II through IV. The role of pulmonary cytology in the diagnosis of low-stage lung cancer is considered in more detail later in this chapter.

In daily practice, however, cytology has very limited application as a screening technique for detecting lung cancer in asymptomatic populations and serves mainly to clarify the nature of lesions in the lung or mediastinum discovered by radiologic examination.

CYTOLOGIC DIAGNOSIS OF BRONCHOGENIC CARCINOMA

Effect of Specimen Collection Method

Sputum and Bronchial Specimens

Cancer cells found in sputum or bronchial secretions originate from loosely bound and often necrotic peripheral cells of the tumor, facing the lumen of the bronchus. They differ significantly from the tumor cells obtained in brush specimens or needle aspirates of more viable tumor.

Thus, the desquamated cells of squamous or SSCs often occur singly, are poorly preserved, and show nuclear condensation or pyknosis. The cytologic diagnosis of cancer in these specimens depends in large part on the interpretation of these poorly preserved tumor cells with the understanding that they are often not representative of the tumor as a whole. These sampling artifacts are consistent and diagnostically very useful, however, and with practice, such cells can be recognized and correctly classified with a high degree of accuracy.

Adenocarcinomas of central bronchial origin shed characteristic tumor cells in clusters. However, the more common peripherally located tumors are unlikely to shed more than a few tumor cells into the bronchus.

In Saccomanno's technique of sputum processing (Saccomanno et al, 1963), described in detail in Chapter 44, the specimen is collected in 50% ethanol with 2% carbowax

P.648

and blended briefly to homogeneity in a Waring blender before preparation of smears from the centrifuged sediment. The morphology of Papanicolaou-stained cancer cells is the same as in direct smears of sputum. There is some evidence, however, that **the diagnosis of SSC based on the distribution of widely separated single cells in Saccomanno's preparations may be more difficult than in conventional smears.**

Bronchial wash and brush specimens collect cells from the surface and the deeper layers of the tumor. Consequently, they exhibit a mixture of viable and poorly preserved or necrotic tumor cells. Squamous and SSCs comprise most of the carcinomas within reach of the bronchial

brush. **Nuclear structure in the viable cells is more transparent and nuclear hyperchromasia is less marked than in desquamated tumor cells found in sputum.** These differences are shown diagrammatically in Figure 20-1.

BAL specimens are designed to sample the distal bronchoalveolar tree (see Chap. 19). In peripheral adenocarcinomas, the lavage specimens may yield well-preserved **single cells and small papillary or flat clusters of large tumor cells.**

Needle Aspirates

In **percutaneous and transbronchial needle aspirates**, the samples are taken directly from the tumor, and usually from its viable portion. A technically good aspirate should contain an abundance of tumor cells, often with small fragments of tumor tissue. The tumor cells in needle aspirates can usually be classified according to tumor type as described below.

Differences in Smear Preparation and Staining Methods

Optimal assessment of cytology of various types of lung cancer is obtained by examining fixed smears stained by the Papanicolaou method. However, air-dried, methanol-fixed smears, stained with Diff-Quik or another hematologic stain are widely used, particularly for percutaneous aspiration cytology. In this type of material, the diagnosis of cancer is usually readily established but **differences among tumor types are less obvious.** The brilliant qualities of cytoplasmic keratin staining, so obvious in Papanicolaou stain, are replaced by a bluish color that may be intense enough to obscure the nuclear structure of the cells. **The description of features that distinguish the types of cancer cells in bronchogenic carcinomas that follows is based on the Papanicolaou stain.** The results with other stains will be briefly noted when needed.

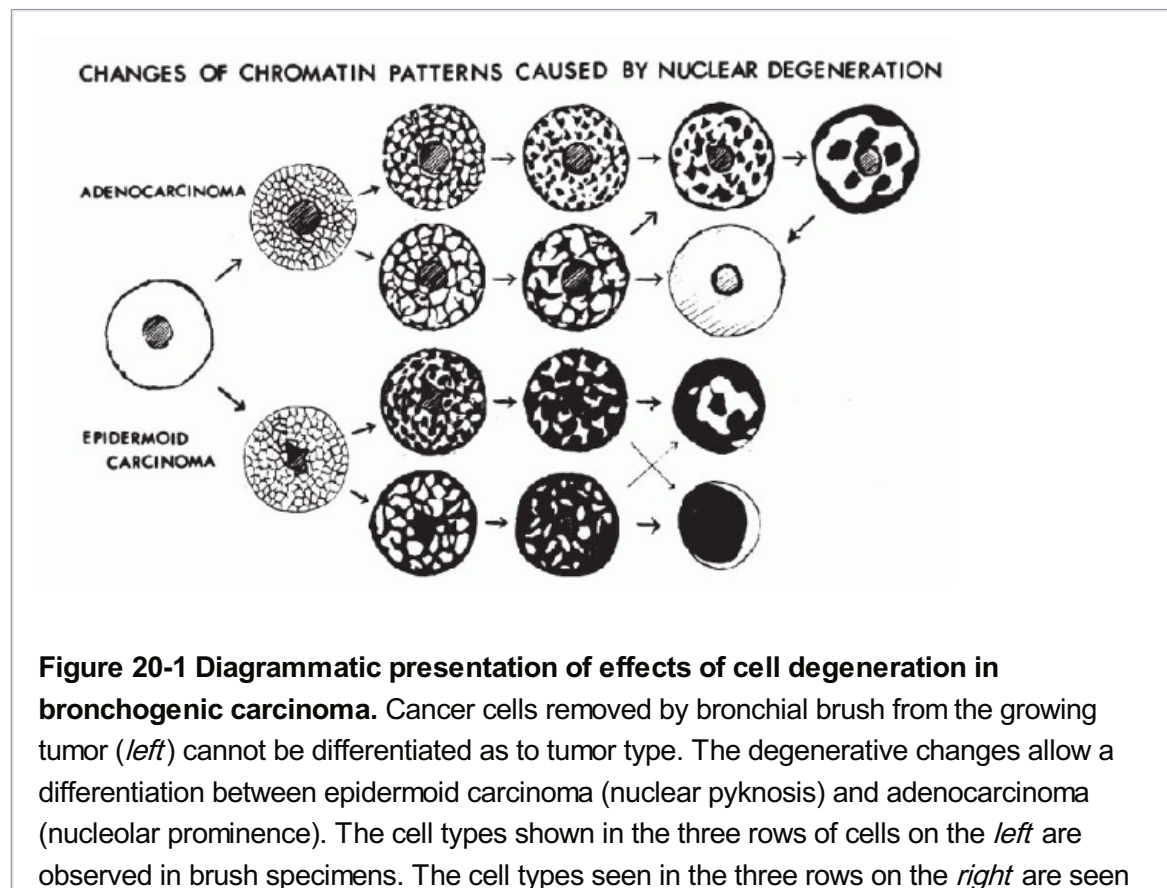

Figure 20-1 Diagrammatic presentation of effects of cell degeneration in bronchogenic carcinoma. Cancer cells removed by bronchial brush from the growing tumor (*left*) cannot be differentiated as to tumor type. The degenerative changes allow a differentiation between epidermoid carcinoma (nuclear pyknosis) and adenocarcinoma (nucleolar prominence). The cell types shown in the three rows of cells on the *left* are observed in brush specimens. The cell types seen in the three rows on the *right* are seen

in sputum. (Courtesy of Dr. Shoji Hattori, Osaka, Japan.)

SQUAMOUS CARCINOMA

Clinical Data

Squamous carcinoma is a common form of primary lung cancer. Afflicting primarily cigarette-smoking men and women older than 50 years of age, these neoplasms originate mainly in the epithelium of secondary or tertiary bronchi (Melamed et al, 1977), and may cause bronchial obstruction. They are twice as frequent in upper lobes as middle or lower lobes; those that arise in the lower lobes are almost always in an upper segment. As they grow, the carcinomas extend proximally from segmental to lobar and eventually the mainstem bronchus (Fig. 20-2A). Cough, with or without hemoptysis, is by far the most common clinical symptom. **In the earliest stages of the disease, radiographic examination of the chest may fail to reveal any significant abnormality. Later, the radiographic abnormalities are of a tumor mass and/or atelectasis or pneumonitis secondary to obstruction of the bronchial lumen.**

Histology

The **well-differentiated**, keratinizing squamous cancers are composed of sheets of cells attempting to form squamous epithelium (Fig. 20-2B), often with abundant keratin formation and keratin pearls. **Central keratinization and necrosis is characteristic, particularly in larger tumors, and may lead to cavity formation within the tumor** (Fig. 20-2C,D).

In poorly differentiated, that is, nonkeratinizing

P.649

squamous carcinomas (also known as epidermoid carcinomas), the cancer cells are usually smaller and keratin formation is less conspicuous, limited to individual cells or focal areas of the tumor. The arrangement of cancer cells in sheets is characteristic of these tumors as well (Figs. 20-2D and 20-5C).

Figure 20-2 Squamous carcinoma. *A.* Gross appearance of squamous carcinoma, which originated in a segmental branch of the upper lobe bronchus and extended proximally into the lobar bronchus. *B.* Histologic section of well-differentiated keratinizing squamous carcinoma. The cancer cells grow in sheets mimicking squamous epithelium, with keratinization and necrosis in the poorly vascularized center of the tumor. *C.* Gross photograph of a cavitating squamous carcinoma. The cavity communicates with a large bronchus. *D.* Histologic section of the cavity wall shown in *C.* The tumor is composed of poorly differentiated squamous cancer cells.

Precursor lesions of squamous carcinoma (e.g., bronchogenic carcinomas in situ), are discussed below in the section on lung cancer detection.

Cytology

Sputum and Bronchial Secretions

Cytologic examination of sputum and/or aspirated bronchial secretions can yield a rapid and accurate diagnosis of squamous lung cancer, regardless whether the tumor is visualized bronchoscopically or not. **Squamous cancer cells** are reminiscent of normal squamous epithelial cells, but differ from normal in several important features.

Abnormalities in Shapes and Sizes

Cells of squamous carcinoma **vary considerably in shape and size**, are typically found in a background of inflammation and necrosis, and often assume a most bizarre appearance (Fig. 20-3A,B). **Spindly cancer cells and tadpole cells** are quite common and their presence is characteristic of these neoplasms (Fig. 20-3B,C). **Very large squamous cells may appear next to very small cells.**

Cytoplasmic Abnormalities

The cytoplasm produces keratin and assumes a **brilliant orange or yellow color in Papanicolaou stain**, with a certain

P.650

quality of **thickness and refractility** that may be brought out when the condenser of the microscope is lowered. The keratin also confers a **very sharp cell outline** (Fig. 20-3A,C). In some degenerating highly keratinized cancer cells, the densely yellow or orange cytoplasm **drowns out a fading nucleus** that is undergoing karyolysis. The resulting abnormally shaped **yellow or orange ghost cells** have only faint outlines of a nucleus, or no nucleus at all (Figs. 20-3D). **In the absence of nucleated cancer cells, the ghost cells in sputum or bronchial specimens are strongly suggestive, although not fully diagnostic of squamous carcinoma.** Only in tracheitis sicca associated with tracheostomy are there likely to be benign squamous ghost cells with nuclear atypia that mimics malignant cells; otherwise the ghost cell nuclei are bland, if at all visible (see Chap. 19).

Nuclear Abnormalities

Although **nuclear hyperchromasia is characteristic and typical**, it does not apply to all squamous cancer cells. As noted, **the nuclei of some cancer cells may be relatively pale**, especially the keratinized or necrotic cells that are undergoing karyolysis ("ghost" cells; Fig. 20-3D). Peculiar **staining characteristics** of the nuclei are evident in tumor cells that are undergoing degeneration. They may sometimes have a **smudgy** or remarkably **homogeneous water color appearance**. **More often, the nuclei are deeply and evenly hyperchromatic, resembling India ink** (Fig. 20-3A-C). This is caused by pyknosis. On closer examination,

chromatin structure is generally visible in such nuclei.

Significant aberrations of nuclear shape are common. Many nuclei are **angular or irregular in configuration** (Fig. 20-3A,C) and commonly variable in size as well as shape. Some have a **bizarre shape** (Fig. 20-3C).

The **nuclear/cytoplasmic ratio** varies considerably in this type of tumor and, although nuclei are on the whole quite large for cell size, there may be some very small pyknotic nuclei as well.

Reversal of the nuclear/cytoplasmic ratio in favor of the nucleus, so characteristic of cancer in general, is not of paramount importance in diagnosing the well-differentiated keratinizing form of squamous carcinoma.

Uncommonly, **abnormal nucleoli** may be noted usually in poorly differentiated epidermoid cancer cells.

P.651

Phagocytosis of Cancer Cells by Cancer Cells

Multinucleated squamous cancer cells are not unusual (Fig. 20-4A) but on occasion, a **complete small cancer cell may be found within the cytoplasm of a larger cell (Fig. 20-4B)**. While cancer cells are sometimes capable of phagocytosis of small particles, carbon or hemosiderin for example, the “cell in cell” phenomenon most likely is the **result of an abnormal mitotic division** with improper separation of the two daughter cells. Phagocytosis should not be confused with **emperipolesis**, the active infiltration of a cell (in this example, tumor cells) by leukocytes (Fig. 20-4C).

Incomplete separation of squamous daughter cells may result in the formation of a **squamous pearl**, that is, a concentrically arranged cluster of cancer cells (Fig. 20-4D). These must be distinguished from similar structures (benign pearls) occurring in the absence of cancer (see Fig. 19-7C). The **difference** lies in the **configuration and staining of the nuclei**, which in the malignant squamous pearls are hyperchromatic and of irregular shape, in keeping with squamous cancer. **The malignant pearl is usually smaller, with fewer cells and greater cytoplasmic keratinization.** Most importantly, in case of doubt, a search for single, clearly identifiable cancer cells in other fields of the specimen usually settles the problem.

Figure 20-4 Squamous cancer cells in cytology samples. *A.* Multinucleated squamous cancer cell. *B.* “Cell in cell” formation of cancer cells, suggesting (incorrectly) phagocytosis. *C.* Emperipolesis, the active entry of lymphocytes or polymorphonuclear leukocytes into the cytoplasm of another cell, often a cancer cell. *D.* Malignant squamous pearl, formed by concentrically layered squamous cancer cells.

Breakdown of Clusters

Squamous cancer has a marked tendency to exfoliate as single cells (see Fig. 20-3A). In fact, one should follow **the general rule that a diagnosis of this tumor type should not be made unless single cancer cells are found**. A dozen or so of the characteristic single tumor cells scattered over one or two smears may be sufficient to establish the diagnosis.

Mitotic Activity

Mitoses are very rare in keratinizing squamous carcinoma. In general, however, mitotic cells in a specimen of pulmonary origin, **although not diagnostic of cancer, call for careful investigation to rule out a malignant neoplasm**.

Cytology of Nonkeratinizing Squamous (Epidermoid) Carcinoma

The nonkeratinizing carcinomas differ primarily in cytoplasmic staining, which in most cancer cells is basophilic

P.652

or amphophilic (Fig. 20-5A,B) and more transparent with less abundant cytoplasm than in keratinizing carcinoma. The nuclei are hyperchromatic with coarsely textured chromatin but usually not pyknotic. Less commonly, nuclear chromatin is more delicate and nucleoli may be visible. It is not unusual in such specimens to find a few keratinizing cancer cells, and these are of value in correctly classifying the tumor (Fig. 20-5B). They are derived from the more ischemic surface (Fig. 20-5C).

Bronchial Brush Specimens and Transbronchial Needle Aspirates

Several of the **key features that identify squamous carcinoma in sputum and bronchial secretions**, such as squamous pearls, keratinization, nuclear pyknosis, and the presence of single cancer cells **may have only scant representation in bronchial brush specimens and transbronchial needle aspirates**. This is particularly evident in poorly differentiated squamous (epidermoid) carcinomas. Cancer cells removed from actively growing peripheral portions of a squamous carcinoma do not exhibit nuclear pyknosis or cytoplasmic keratinization as found in the center of the tumor or at the bronchial surface (see Figs. 20-2B and 20-5C). **The viable, replicating tumor cells in an FNA occur in sheets or loose clusters wherein the cell outline may be ill-defined and the cytoplasm is cyanophilic (basophilic) rather than eosinophilic. The nuclei are large, coarsely granular, and may be hyperchromatic, but are rarely pyknotic.** There may be visible or even prominent nucleoli. On occasion, thick cell clusters can assume a pseudopapillary configuration. Thus, bronchial brush and particularly FNA specimens of keratinizing and non-keratinizing squamous cancers may be very much the same.

Figure 20-5 Poorly differentiated (nonkeratinizing) squamous carcinoma in sputum (A) and bronchial brush (B) specimens. The nuclei are hyperchromatic, coarsely textured and irregular. The tumor cells in sputum have scanty, pale eosinophilic cytoplasm, while in the bronchial brush specimen, they have amphophilic or sometimes basophilic cytoplasm. C. Junction of viable (*lower*) and nonviable (*upper*) tumor, the latter at the surface of the bronchus of origin. The condensed and hyperchromatic pyknotic nuclei are present in the necrotic portion of the tumor.

In the absence of keratinization and nuclear pyknosis, as may be the case in poorly differentiated squamous (epidermoid) carcinoma, or if direct bronchial brushings or needle aspirates sample nonkeratinized areas of tumor, the distinction between a poorly differentiated squamous carcinoma and adenocarcinoma may be difficult. **In such cases, it is best to report the cytologic diagnosis as “positive for malignant cells, undifferentiated large-cell carcinoma,” or as “non-SSC.”** The principal differences between the cytologic presentation of exfoliated cells of squamous carcinoma in sputum and direct samples of tumor in bronchial brush specimens and transbronchial aspirates are summarized in Table 20-2.

Percutaneous Needle Aspirates

Squamous lung cancers usually arise in the secondary or tertiary bronchi. Most are centrally located and are accessible to bronchoscopic study. In our experience, peripheral squamous cancers are quite uncommon and the majority are nonkeratinizing. Percutaneous aspiration biopsy may be needed for those few cases. The aspirate yields cells with large nuclei and variably stained cytoplasm that is

P.653

only moderate or sometimes scanty in amount. Nuclear chromatin may be coarse and hyperchromatic or more delicate with visible or even prominent nucleoli. Differentiation from large-cell carcinoma or adenocarcinoma is frequently difficult or impossible. Except for the extremely uncommon **keratinizing peripheral squamous cancers, which yield classic keratinized cancer cells, most of the nonglandular peripheral cancers are best classified as poorly differentiated large-cell carcinoma** (discussed later).

TABLE 20-2 SQUAMOUS CARCINOMA: PRINCIPAL DIFFERENCES IN THE CYTOLOGY OF CANCER CELLS IN SPUTUM VERSUS BRONCHIAL BRUSH SPECIMENS AND TRANSBRONCHIAL NEEDLE ASPIRATES

Cytologic Presentation	Sputum	Bronchial Brush and Transbronchial Needle Aspirates
Presence of cancer cells	Variable, may be few	Usually many
Cytoplasmic keratinization	Marked	Confined to a few cells; often absent
Abnormal N/C ratio	Variable	More commonly increased
Nuclear pyknosis	Marked	Not marked; often absent
Single cancer cells	Frequent	Infrequent
Cancer cells in clusters	Infrequent	Predominant
Nuclear structure detail	Difficult to see	Readily visible
Nucleoli	Inconspicuous or absent	Commonly visible and may be prominent

Correlation of Cytology With Histology in Keratinizing Squamous Lung Cancer

Because of selective sampling from the exposed surface of the tumors in sputum and bronchial washings, or if the periphery of the tumor is sampled in an FNA, **a dominant cell population of keratinized cancer cells in the former case, or their absence in the latter, may not accurately reflect the histology of the tumor.** Bronchial brushings or needle aspirates from the core of the tumor are generally more representative.

Squamous Lung Carcinoma Following Laryngectomy for Carcinoma

Cahan and Montemayor (1962) have shown that the incidence of squamous lung cancer is greatly increased in patients who have had prior cancers of the upper air passages, mainly the larynx. To secure cytologic material from patients who have had a laryngectomy for carcinoma and are left with a permanent tracheostomy, they obtained **tracheobronchial washings via the tracheal stoma.** In a survey of 308 such patients, there were 12 with positive cytology: 6

had metastatic carcinoma, but 6 had new primary cancers of the lung, and in 4 of those patients, cytologic evidence preceded radiographic suspicion (Cahan et al, 1966). However, one must be warned that cells derived from the metaplastic squamous epithelium of tracheitis sicca (dry tracheitis) in patients with a permanent tracheostomy can sometimes mimic squamous carcinoma (see Chap. 19).

Determining the Site of Origin of Squamous Carcinoma

The histologic and cytologic presentation of bronchogenic squamous carcinoma is not unique. Tumors of identical morphology arise in the oral cavity, esophagus, and upper respiratory tract, not uncommonly as multiple, separate, simultaneous or sequential cancers of squamous origin. Metastatic carcinomas from more distant sites may also mimic primary bronchogenic squamous carcinoma, including, for example, carcinomas of bladder, uterine cervix, and the exceedingly rare squamous cancers of endometrium or breast. Thus, **cytologic evidence of squamous carcinoma in sputum, and even in samples taken directly from the lower respiratory tract, does not automatically indicate bronchogenic origin.** Clinical correlation is essential. Localization procedures in patients with occult bronchogenic carcinoma and carcinoma in situ are discussed below.

Differential Diagnosis of Bronchogenic Squamous Carcinoma

Diagnostic difficulties may be encountered in differentiating **nonneoplastic atypias of squamous cells of buccal, laryngeal, or tracheal origin** from bronchogenic squamous

P.654

carcinoma (see Chap. 19). These difficulties can be minimized by attention to clinical data and a careful evaluation of cellular detail. **A history of prior or concurrent radiation treatment or prior laryngectomy should caution against the diagnosis of squamous carcinoma on limited evidence.** Other sources of possible error include vegetable (plant) cells, droplets of condensed mucus, and **epithelial atypias** associated with nonneoplastic disorders such as **pulmonary mycetomas** or **pemphigus**, all discussed in Chapters 19 and 21.

Tumor cells of other types that sometimes exhibit cytoplasmic eosinophilia in the Papanicolaou stain may mimic squamous or epidermoid carcinoma. This can occur with other forms of lung cancer and with metastatic cancers to the lung.

Large-Cell Undifferentiated Carcinoma

Histology

The large-cell undifferentiated bronchogenic carcinomas are composed of broad, diffusely infiltrating **sheets of usually moderate size tumor cells with moderate- to abundant cytoplasm** (Fig. 20-6A). Many of these tumors are peripheral in origin and/or unrelated to major bronchi, and we believe they most likely represent undifferentiated adenocarcinomas. **By definition, they are without substantial squamous or glandular differentiation**, although they may exhibit focal features of squamous cancer or adenocarcinoma, sometimes side by side. They are derived from the same basal epithelial cells (reserve cells) that give rise to squamous and adenocarcinomas. Tateishi and Hattori (1982) considered these tumors to be undifferentiated carcinomas that lacked either light microscopic or ultrastructural evidence of maturation to other cell types, but Kodama et al (1985) found ultrastructural evidence of both glandular and, less commonly, squamous differentiation. As a practical point, more specific classification is irrelevant at this time, since all non-small-cell lung

cancers have the same prognosis and are treated in the same way.

Figure 20-6 Undifferentiated large-cell (non-small-cell) carcinoma in peripheral lung. *A.* In this histologic section, the cancer cells are growing in sheets and have abundant, pale eosinophilic cytoplasm. Sputum (*B*) and bronchial brush (*C*) with cells from an undifferentiated large-cell carcinoma showing variations in staining pattern. The nuclei are either hyperchromatic with coarsely textured chromatin within the pale-staining cytoplasm (*B*), or have a more delicate chromatin structure with prominent nucleoli, resembling adenocarcinoma (*C*). A percutaneous FNA (*D*) shows sheets of large tumor cells with abundant cytoplasm corresponding to the histologic section shown in *A*.

Cytology

The tumor cells, although frequently single, have a marked tendency to form loosely structured clusters composed of

P.655

cells of unequal sizes. Cells within the clusters are seldom superimposed; commonly, they lie flat next to each other (Fig. 20-6B,C). While some have little cytoplasm, most of the tumor cells are characterized by ample cytoplasm and they are comparable in size either to the cells of squamous carcinoma or adenocarcinoma. The cytoplasm is usually pale staining and delicate in appearance, and may be eosinophilic or basophilic. On rare occasions, **small red intracytoplasmic inclusions** are noted; they are wholly **comparable to those observed in urinary sediment** (see Chap. 22) and have no diagnostic significance. **The nuclei are large, sometimes of irregular contour, and sharply outlined.** They are characterized by **coarse hyperchromatic chromatin** (Fig. 20-6B), or frequently by **fine chromatin and single or multiple prominent nucleoli** (Fig. 20-6C), and rarely are pyknotic. Thus, the nuclear structure is more reminiscent of an adenocarcinoma (see below) than squamous carcinoma. Occasional **papillary cell clusters and cytoplasmic vacuoles may suggest differentiation toward adenocarcinoma.**

Sputum and Bronchial Brush Specimens

In this tumor type, the differences in cytologic presentation between sputum and bronchial brush specimens are not as marked as in keratinizing carcinoma. **The main features of the tumor cells, as described above, are observed in sputum and brush specimens.** The tumor cells more often form groups and clusters in brush specimens than in sputum. **Nuclear structure** is usually well preserved. The nuclear envelope often shows indentations and protrusions, resulting in **irregular nuclear contours**. The nuclei show **one or more large nucleoli** (Fig. 20-6C). **In the absence of keratinization, the differential diagnosis lies between undifferentiated large-cell carcinoma and adenocarcinoma and may be difficult to establish.** Fragments of tissue embedded in paraffin and processed as a cell block may facilitate the identification of tumor type.

Percutaneous and Transbronchial FNAs

Undifferentiated large-cell carcinomas are among the **easiest to identify as malignant because of the size of the cancer cells and their often-striking nuclear abnormalities**, which include **abnormal shapes and either coarse granulation of chromatin or more delicate chromatin with prominent nucleoli**. In needle aspirates, the tumor cells may be in sheets (Fig. 20-6D) or dispersed. **In air-dried, methanol-fixed smears stained with Diff-Quik or similar stains**, the nuclei of the tumor cells are large, but nuclear features are poorly visualized and the cytoplasm, which stains pale blue, has no definable structure. The differential diagnosis of non-SSC **should include primary and metastatic adenocarcinoma and attention should be directed to any history of previously treated cancer.**

Sources of Diagnostic Error

Except for markedly atypical squamous metaplasia (“repair”), radiation effect and drug effect (see Chap. 19), **there are virtually no benign cell abnormalities that could lead to a mistaken diagnosis of undifferentiated large-cell bronchogenic carcinoma.**

SMALL CELL CARCINOMA (SCC)

Clinical Features

In prior classification schemes, these highly aggressive malignant tumors were divided into two subgroups: **classical oat cell carcinoma**, and an **intermediate cell type of SSC**. Because these two subtypes do not differ clinically, the latest **World Health Organization (WHO) classification combines both subtypes as SCC** (Travis et al, 1999). The term **combined SSC** is used for the not uncommon occurrence of SCC with any non-small-cell component, for example, squamous, adenocarcinoma, or large-cell carcinoma.

However, there are **distinct cytologic differences between the small and intermediate cell types of SSC**, based on cell size and other morphologic characteristics, that are of importance in cytologic diagnosis. Though not recognized in the 1999 WHO classification, the distinction is important for our diagnostic purposes and the two subtypes will be described separately.

SSCs, as a group, share some important characteristics. These tumors, even when of very small size, **may induce endocrine paraneoplastic syndromes** because of active production of a broad variety of polypeptide hormones, including adrenocorticotropin (ACTH), antidiuretic hormone, parathormone, calcitonin, and gonadotropins. The clinical syndromes include **Cushing's syndrome, water retention, hypo- or hypercalcemia** (hypercalcemia is more

commonly associated with squamous lung cancer), **gynecomastia, and antibody-induced central nervous system (CNS) disturbances with bulbar and cerebellar degeneration.** The CNS syndrome is induced by a polyclonal IgG (anti-Hu) antibody that binds to nuclei of SSC and of the affected neurons (Anderson et al, 1988; Rosenblum, 1993; Gultekin et al, 2000). The neurologic disorder may precede first clinical evidence of carcinoma. Thus, although hormone production has been demonstrated by immunohistochemistry in nearly one third of all lung carcinomas (Dirnhof et al, 2000), the **paraneoplastic syndromes are most common in SSC.** It is essential that patients presenting with suspicion of a paraneoplastic syndrome undergo careful evaluation for a possible malignant tumor (Mizutani, 1988; Nathanson and Hall, 1997), and cytology may play an important role in the workup of these patients.

Because of the frequency of associated endocrine syndromes, it has been widely **assumed that SSCs are part of the spectrum of neuroendocrine tumors** (Colby et al, 1995),

P.656

related to carcinoid tumors, and derived from the Kulchitsky cells, that is, the endocrine bronchial cells (Bensch, 1965). **Neuroendocrine cytoplasmic granules can be observed by electron microscopy** in both the carcinoids and SSCs (Bensch et al, 1968; Nomori et al, 1986); however, they are **numerous in carcinoid tumors and few in oat cell carcinomas.** It is not unusual to find a few neuroendocrine granules in other lung cancers that are not considered to be of neuroendocrine origin, and their presence in oat cell carcinoma may simply represent aberrant differentiation. Although immunohistologic stains for neuroendocrine markers such as synaptophysin may be positive, we have found the **stains for chromogranin are typically negative in oat cell carcinoma and consistently positive in carcinoid tumors** (Zaman, unpublished data). For other studies of oat cell carcinomas and carcinoids, see Fisher et al (1978).

The **epidemiology of oat cell carcinoma and carcinoid are markedly different** (Godwin and Brown, 1977). SSCs are highly aggressive, rapidly growing, and widely metastasizing malignant tumors that rarely are cured by surgery, unlike the very slowly growing carcinoids that typically evolve over a period of many years with high rates of cure by surgical excision. They differ also in **gene expression profiles recently studied with cDNA arrays that clearly indicate small-cell (oat cell) carcinomas are related to and are most likely derived from bronchial epithelial cells, whereas the bronchial carcinoids are neural-crest derived** (Anbazhagan et al, 1999). In a long-term study of uranium miners and others at risk of lung cancer Saccomanno et al (1974) described several patients with **cytologic evidence of squamous carcinoma in situ preceding the development of oat cell carcinoma.** It is therefore **quite likely that SSCs of the lung are epithelial tumors derived from the epithelium of the bronchi and not from endocrine cells.** It must be assumed that the paraneoplastic syndromes occurring in SSCs (and occasionally in squamous and other lung cancers) reflect the ability of epithelial bronchial cells to produce polypeptide hormones, accounting for the clinical manifestations.

Until about 1975, the prognosis of SSC, whether treated or untreated, was nearly hopeless, with rapid dissemination and death from disease occurring within a few months of diagnosis. Aggressive irradiation and multidrug therapy introduced and improved over the last quarter of a century may eradicate the primary tumor and some metastases, significantly extending survival (Perry et al, 1987), but remission is temporary and widespread seeding to distant organs including the CNS is common. **Carcinomatous meningitis is a fairly common complication**

in patients treated for SSC (Balducci et al, 1984; Strady et al, 2000), **and may superficially resemble meningeal involvement by leukemia or lymphoma; cytologic examination of cerebrospinal fluid is of paramount importance in establishing the diagnosis** (see Chap. 27). Prophylactic radiotherapy of the CNS in patients with remission has decreased the risk of brain metastases and further increased 3-year survival (Auperin et al, 1999). Because the treatment of **small-cell lung cancer is different from that of non-SSCs**, **an accurate diagnosis of this tumor is essential and represents a major challenge in cytopathology.**

Oat Cell Type

Histology

SSCs arise from lobar or major segmental bronchi, similar in origin to squamous carcinomas. In contrast to the more slowly growing squamous carcinomas, SCC metastasizes early to hilar and mediastinal lymph nodes, and disseminates widely via the blood stream.

For many years, this rapidly fatal malignant tumor was considered by some to be a small cell sarcoma. James Ewing (1922) classified it as a “peribronchial sarcoma,” a testimony to its anaplastic appearance. Even today, the correct diagnosis is not always easy, especially in biopsies of metastatic sites or when tissue or cytologic samples are scanty.

Histologically, small-cell (oat cell) carcinoma is composed of **sheets of small, round, ovoid, or spindly cells that characteristically seem separated from each other, and have been compared to grains of oats**; hence, the widely accepted name. The “oat cell” appearance of these tumor cells is exaggerated by tumor **necrosis, which is extremely common** (Fig. 20-7A). There may be **“crushing artifact” in biopsies, or streaks of hematoxylin-stained nuclear material (Azzopardi effect)**, which is extremely characteristic of this tumor. In **well-fixed tumor tissue**, the sheets of tumor cells take on an **epithelial configuration**, often with **poorly formed glandular or tubular structures, rosettes, or islands of larger cells**. In some cases, SSC may assume a **lobular growth pattern with peripheral palisading of tumor cells, resembling and sometimes referred to as basaloid carcinoma** (Brambilla, 1992; Dugan, 1995). All variants of SSC have the same aggressive clinical course, and it is doubtful whether they deserve separate classification.

In keeping with their origin in the reserve cells of the bronchial epithelium, oat cell carcinomas may exhibit foci of glandular or squamous differentiation, and conversely the anaplastic squamous and adenocarcinomas of lung may mimic oat cell carcinoma. The term **combined SSC** is reserved for those tumors that have a **dominant pattern of SSC with a substantial component of other tumor types**.

Frequent genetic abnormalities observed in SSCs include a loss of the short arm of chromosome 3. Rarely, this abnormality may also occur in non-small-cell cancers (Brauch et al, 1987; Dennis and Stock, 1999).

Cytology

Sputum and Bronchial Secretions or Washings

Oat cell carcinoma may be difficult to diagnose because, at low (scanning) magnification, **the small cancer cells can**

P.657

be misinterpreted as lymphocytes or may entirely escape the attention of an

inexperienced observer (Fig. 20-7B). However, the cytologic presentation of this tumor is very characteristic and, once the hurdle of initial recognition has been overcome, the diagnosis is quite easy and accurate. This is of considerable importance to the clinician for reasons discussed above.

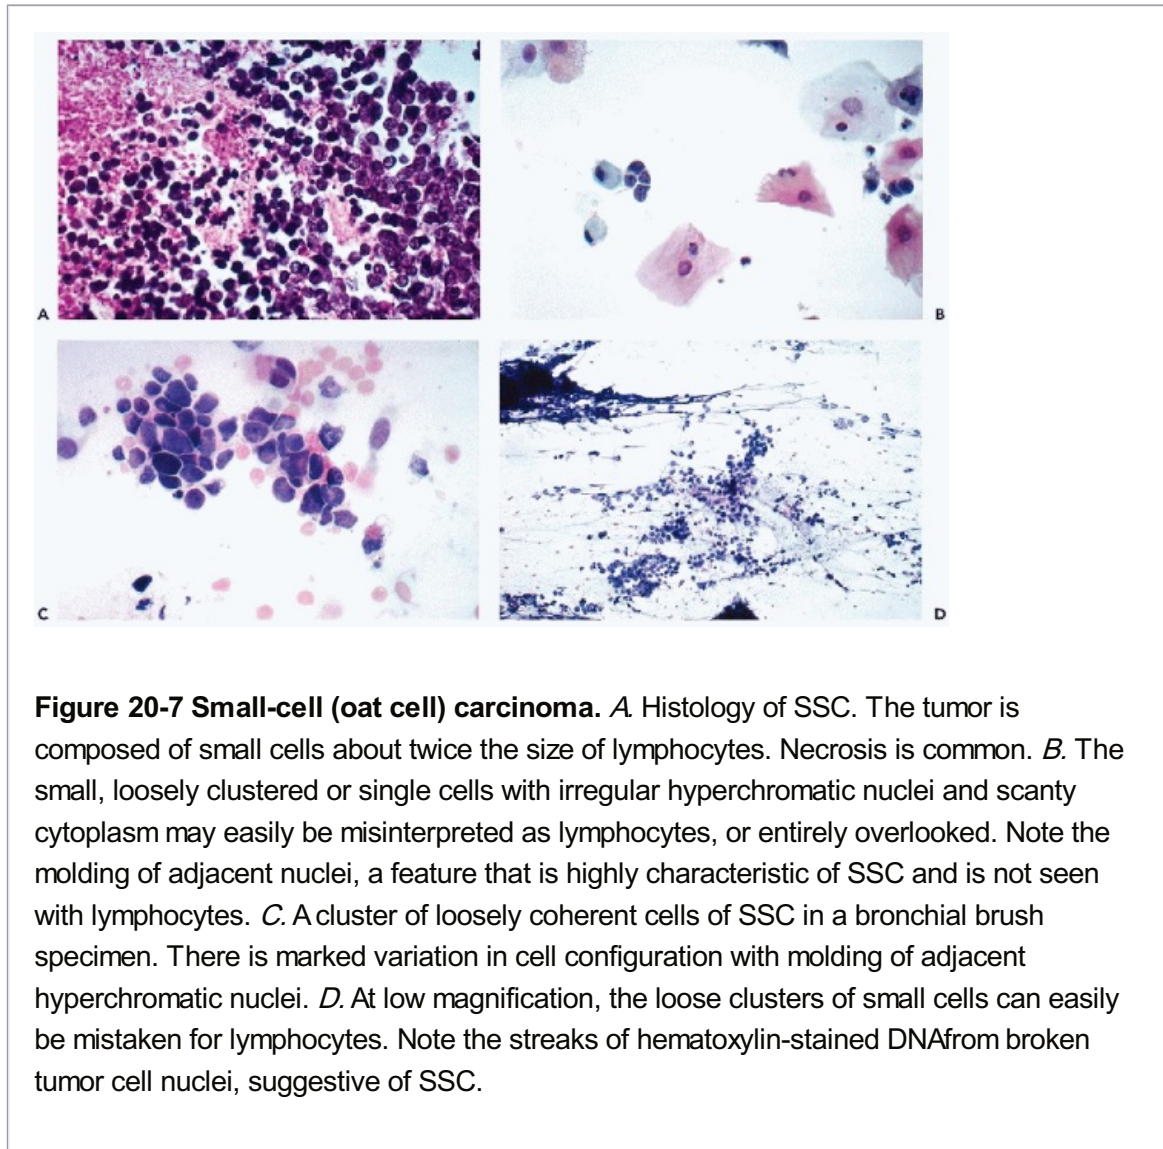

Figure 20-7 Small-cell (oat cell) carcinoma. *A* Histology of SSC. The tumor is composed of small cells about twice the size of lymphocytes. Necrosis is common. *B*. The small, loosely clustered or single cells with irregular hyperchromatic nuclei and scanty cytoplasm may easily be misinterpreted as lymphocytes, or entirely overlooked. Note the molding of adjacent nuclei, a feature that is highly characteristic of SSC and is not seen with lymphocytes. *C*. A cluster of loosely coherent cells of SSC in a bronchial brush specimen. There is marked variation in cell configuration with molding of adjacent hyperchromatic nuclei. *D*. At low magnification, the loose clusters of small cells can easily be mistaken for lymphocytes. Note the streaks of hematoxylin-stained DNA from broken tumor cell nuclei, suggestive of SSC.

Sputum processed by the “pick-and-smear” technique is superior to Saccomanno's technique in the diagnosis of this tumor type (see Chap. 44). **Oat cell carcinomas shed loosely arranged clusters of small cells of variable sizes, somewhat larger than lymphocytes**, with molding of adjacent or superpositioned nuclei that are pressed together (Fig. 20-7B,C). In bronchial washings and aspirates, the tumor cell clusters are usually more cohesive than in sputum, and overlapping nuclei and flattening or “molding” of adjacent cells are more common.

Although the tumor cells are small, they have relatively large nuclei, larger than lymphocytes, and a very scanty rim of cytoplasm. The cytoplasm is usually basophilic, but on occasion may exhibit eosinophilia, suggesting keratin formation. Often, the tumor cells are present as **bare nuclei**, or with only a small amount of adherent cytoplasm. Tumor cell necrosis is common.

Bauer and Erozan (1982) reported **psammoma bodies** in a case of SSC.

Bronchial Brush Specimens

There is better sampling of viable tumor in bronchial brush specimens than in sputum or bronchial washing, and a **greater proportion of well-preserved, viable tumor cells**. The tumor cells are variable in size, although they are generally small with very scanty cytoplasm. **The molding of adjacent nuclei in clusters of tumor cells (Fig. 20-7C) is very common.** **Two types of nuclei may be observed: hyperchromatic or pyknotic nuclei and nuclei that are open or vesicular.** The best-preserved tumor cells have a coarsely granular nuclear pattern, and some may have small, discernible nucleoli. The cells with pyknotic nuclei are derived from necrotic parts of the tumor, whereas tumor cells with vesicular nuclei are from nonnecrotic tumor

P.658

sampled by brushing. This feature will be illustrated and discussed below with the intermediate type of SSC. The nuclei are fragile and, regardless of the care with which the specimen has been obtained, **nuclear breakdown is extremely common.** This “crush artifact” results in smudges and streaks of nuclear material that is of diagnostic value since this type of necrosis is uncommon in other tumors (Azzopardi effect) (Fig. 20-7D). Sturgis et al (2000) ranked cell size, scanty cytoplasm, and nuclear molding as the most useful diagnostic features. Hyperplastic basal cells can be confused with oat cell carcinoma, but are smaller, more uniform without necrosis, and typically in coherent clusters (see Chap. 19).

Percutaneous Fine-Needle Aspirates

Although most oat cell carcinomas are located in major bronchi and can be diagnosed by sputum or bronchial brush, a small number of the tumors are peripheral and are best sampled by percutaneous biopsy. The cellular features described above for bronchial brush specimens are usually observed in needle aspiration biopsy smears as well. Groups of tumor cells are more common and cell detail is obscured, except in the loosely coherent single cells at the periphery of such clusters. Of special note, **there may be short chains of cancer cells in needle aspirates of oat cell carcinoma (Fig. 20-8B), often with flattening (molding) of adjacent cells.** **Visible nucleoli are uncommon.** In some aspirates, the well-preserved cells dominate and differentiation of oat cell carcinoma from intermediate-type SSC is not possible (see below).

Figure 20-8 SSC, intermediate cell type. *A.* Histologic pattern showing closely packed tumor cells, somewhat larger than oat cell carcinomas but smaller than epidermoid and adenocarcinoma. The cells have more vesicular nuclei and more abundant cytoplasm than oat cell carcinoma, and may be polygonal or spindle-shaped; pyknotic nuclei are few. *B.* Bronchial aspirate showing a streak of nuclei with only wisps of cytoplasm. The hyperchromatic, coarsely textured nuclei, usually provided with one or more chromocenters or a small nucleolus, vary in size but are two to three times larger than a lymphocyte. *C.* Dispersed and loosely aggregated nuclei in a bronchial brush specimen. Nuclei have a vesicular chromatin pattern and clearly evident nucleoli. *D.* Single-cell necrosis and apoptosis are characteristic of SSC.

Intermediate Type

Histology

These tumors resemble oat cell carcinomas except for their **somewhat larger size, more cytoplasm, more vesicular nucleus, and considerably less necrosis** (Fig. 20-8A). Their behavior is the same as that of oat cell carcinoma. In some cases, this tumor type may be mistaken for a small-cell adenocarcinoma or poorly differentiated epidermoid carcinoma, both of which have very different clinical significance.

P.659

Cytology

Sputum and Bronchial Secretions or Washings

The cells desquamating from intermediate type SSC are similar to those of oat cell carcinoma, but are **somewhat larger, with more cytoplasm, and larger nuclei with finer chromatin structure. There are fewer pyknotic nuclei and less necrosis of tumor cells than in classical oat cell carcinoma. They may form cohesive sheets or structures** suggesting adenocarcinoma; in the Papanicolaou stain, the eosinophilic cytoplasm of some cells may be retained, suggesting kinship to epidermoid carcinoma (Fig. 20-8B).

Bronchial Brushings and Fine-Needle Aspirates

In these specimens, the cancer cells of intermediate type SSC present with a **fairly monotonous population of small, spherical, ovoid or elongated cancer cells, singly or in short groups, with vesicular or hyperchromatic, coarsely granular nuclei** (Fig. 20-8C). Small nucleoli may be present. The synchronous presence of both open and pyknotic nuclei is characteristic of this tumor type (Fig. 20-8D). Other characteristics that apply to both types of nuclei include **markedly irregular configuration and marked anisonucleosis. Karyorrhexis (apoptosis) and necrosis is not uncommon** (Fig. 20-8D), **but usually not with the streaks of nuclear material seen in oat cell carcinoma.**

These tumor cells may have a clearly visible rim of pale cytoplasm and, as noted above, they may have features suggesting epidermoid or adenocarcinoma. Focal glandular or epidermoid differentiation, as is sometimes found in these tumors, does not affect treatment.

The subclassification of intermediate type SSC into polygonal or fusiform variants proposed by Zaharopoulos et al (1982) and sometimes seen in histologic sections (Fig. 20-8A) is no longer used.

Sources of Diagnostic Error

- **Basal cell hyperplasia:** Clusters of small cells originating in areas of basal cell hyperplasia of the bronchial mucosa (see Chap. 19) may be mistaken for SSC. However, these compact clusters of uniform cells, in some cases with peripheral columnar differentiation, are readily distinguished from SSC.
- **Atypical basal cell hyperplasia** may occasionally present a diagnostic problem since it can include reactive cells with variable size nuclei and small nucleoli. However, **the cells are usually dislodged in tight clusters or fragments of epithelium, unlike SSCs**. The absence of single cancer cells strongly suggests a benign abnormality.
- **Lymphocytes:** Clusters of lymphocytes seen in follicular bronchitis also may suggest oat cell carcinoma, but they do not form coherent groups and are easily distinguished from epithelial cells. They consist of a usually mixed population of mature lymphocytes and lymphoblasts, smaller than the cells of oat cell carcinoma, without nuclear pyknosis or necrosis (see Chap. 19).
- **Lymphoma:** Differentiation of intermediate type SSC from **large-cell lymphoma** may present some difficulty. **The cells of lymphoma are generally well preserved and distinctly separate without molding. They are more uniform than cells of SSC, and have nuclei with invaginations and protrusions, often with prominent nucleoli** (see below). The viable cells of carcinoma have nuclei that are more smoothly configured.
- **Carcinoid tumors:** The cells of carcinoid tumors are found in sputum only after bronchoscopy or other trauma. In bronchial brushings and percutaneous aspirates, **the tumor cells** are larger than the cells of SSC and form tightly coherent clusters with abundant well-preserved cytoplasm. Tumor cell necrosis is absent (see below).
- **Small-cell malignant tumors** that are morphologically identical with bronchogenic oat cell carcinoma occur in other organs (Gerald et al, 1991; Parkash et al, 1995) and are capable of metastases to the lung. Their cytologic presentation may be identical with that of oat cell carcinoma.

Tumor cells closely resembling oat cell carcinoma may be observed in pulmonary cytology from children with lung metastases of neuroblastoma, embryonal rhabdomyosarcoma, Ewing's tumor, and Wilms' tumor. Because SSC of lung is not seen in childhood, the diagnosis of metastatic cancer is virtually ensured.

ADENOCARCINOMA

Clinical Presentation

Adenocarcinoma of the lung is clearly associated with cigarette smoking, and has been increasing in frequency both in male and female cigarette smokers. Two forms of pulmonary adenocarcinoma may be differentiated on histologic and clinical grounds: **adenocarcinomas of so-called central bronchial origin and peripheral bronchioloalveolar or terminal bronchiolar carcinomas**. Both types begin within the lung parenchyma.

For didactic purposes, **the different histologic patterns of pulmonary adenocarcinoma**

and their cytologic presentation are described separately. In practice, except for some bronchioloalveolar carcinomas, cytologic separation of the two subtypes is seldom possible.

Many, perhaps most, of these patients are asymptomatic at the time of diagnosis. The carcinomas are discovered by chest x-ray taken as part of a routine physical examination or at the time of hospitalization for other disease. The patients who are symptomatic with chest pain, dyspnea, or hemoptysis usually have advanced disease.

The diagnosis of adenocarcinoma calls for an evaluation of tumor location, size and extent, and metastatic status to

P.660

determine surgical resectability. So far, the response of these tumors to chemotherapeutic agents has been modest at best, and the best hope of cure is through early detection and surgical resection.

Adenocarcinomas of Central Bronchial Origin

Histology

In the 1999 WHO classification of lung tumors, adenocarcinomas of central bronchial origin were subclassified into **acinar, papillary, and solid subtypes** (Travis et al, 1999). Although the exact site of origin of these tumors is still not certain, most are peripheral (Fig. 20-9A) and probably arise in **epithelium of sub-segmental bronchial branches or bronchioles**. A small number are of **mucus-gland origin**. There is no difference in management or prognosis of the different subtypes of adenocarcinoma. The **localized tumors** are commonly associated with areas of pulmonary fibrosis or scar. They either arise in the **vicinity of old scars or develop areas of scarring within ischemic parts of the tumor**; present evidence supports the latter view in most cases. The histology and growth patterns of localized adenocarcinoma are similar to those of adenocarcinomas elsewhere in the body, and may be difficult to distinguish from metastatic tumor. The issue of precursor lesions for bronchogenic adenocarcinoma is discussed below.

Figure 20-9 Adenocarcinoma of lung. *A.* Adenocarcinoma, arising in peripheral lung parenchyma adjacent to and invading a major segmental bronchus. *B.* Acinar adenocarcinoma of lung, associated with a desmoplastic reaction, is histologically indistinguishable from adenocarcinomas of other organs. *C.* Papillary adenocarcinoma of lung. *D.* Solid growth pattern of a clear cell adenocarcinoma of lung. An occasional tumor cell is mucicarminophilic (not shown).

The tumors may be **glandular (acinar)** in configuration (Fig. 20-9B), **papillary** (Fig. 20-9C), or composed of **solid nests or sheets of clear cells with intracellular mucin, usually in a few of the cells** (Fig. 20-9D). Solid sheets of tumor may show central (comedo) necrosis. Very often, there is a **combination of patterns**. Uncommonly, the tumors are exuberantly productive of mucin and are grossly gelatinous (Fig. 20-10A,B).

Adenocarcinomas with solid growth pattern are distinguished from large-cell carcinoma by the presence of mucus within at least some tumor cells. The distinction is of little practical importance because prognosis and treatment are not affected. It may be that many, if not most, undifferentiated large-cell carcinomas are adenocarcinomas of solid growth pattern. Regardless of histologic pattern, **the tumor cells vary in shape from polygonal to cuboidal to columnar.**

In 1976, Harwood et al described a **rare form of peripheral pulmonary adenocarcinoma, imitating mesothelioma.**

P.661

Figure 20-10 Adenocarcinoma of lung. *A.* Gross appearance of mucinous (gelatinous) adenocarcinoma. *B.* Histology: strips and scattered mucin-secreting cells within a lake of mucus. *C.* Bronchioloalveolar carcinoma spreading diffusely throughout both lungs (autopsy specimen). *D.* Histologic section of the type I tumor shown in *C.* The tumor cells are columnar with basal nuclei, growing upon the intact alveolar framework. There is no destruction of lung tissue.

Cytology

Sputum and Bronchial Secretions

There are no consistent differences in the cytologic presentation of the subtypes of central adenocarcinoma. The exfoliated **cancer cells** in sputum and bronchial secretions are **large, usually round or polygonal, occasionally columnar**, and are found in **clusters** or **singly** in sputum and bronchial wash specimens. The cell clusters have a three-dimensional **papillary** or approximately **spherical configuration** with tumor cells superimposed upon each other (Fig. 20-11A,B). **Cytoplasm of the cancer cells may be scanty or stripped away, but in well-preserved cells, it is moderate in amount, often finely vacuolated and faintly staining, usually basophilic. Single vacuolated tumor cells** may be mistaken for macrophages, **and on rare occasions are phagocytic**, but they have the nuclear features of cancer cells (Fig. 20-11C). Such cells are seen in the lumens of adenocarcinoma in histologic sections and represent desquamated, degenerating, mucinsecreting tumor cells. The larger mucin vacuoles often seem to displace the nucleus to one side, sometimes causing it to bulge out of the cell (Fig. 20-11C and 20-12C). This does not happen with histiocytes. We have occasionally observed **lipid-containing vacuolated macrophages** accompanying the tumor cells of adenocarcinoma, consistent with an endogenous lipid pneumonia (see Chap. 19). Macrophages may also contain phagocytized mucin, but this is unusual and a positive mucicarmine stain can be of help in confirming the identity of mucin-secreting cancer cells.

In a phenomenon known as **emperipolesis**, tumor cells may be infiltrated by leukocytes (Fig. 20-11D).

The nuclei of pulmonary adenocarcinomas are best studied in single cancer cells. They are large for the size of the cells, with finely granular chromatin and usually slight to moderate hyperchromasia, **often with prominent, single or multiple nucleoli**. There may be **indentation of the nuclear membrane and sometimes an invagination of cytoplasm into the nucleus, forming the so-called nuclear holes** (Fig. 20-12A). **Multinucleation** is common. Nuclear pyknosis is rare.

Primary adenocarcinoma of the lung may be difficult to differentiate from anaplastic carcinoma of large-cell type, particularly if the tumor is represented by single cells without cell clusters. The presence of papillary clusters or columnar cancer cells clearly favors the diagnosis of adenocarcinoma.

P.662

Figure 20-11 Cytology of adenocarcinoma of lung. *A,B.* Clusters of overlapping tumor cells with scanty, pale cytoplasm, relatively large nuclei, finely textured chromatin and prominent nucleoli. *C.* Single cancer cells with abundant finely vacuolated cytoplasm may mimic histiocytes, but are distinguished by nuclear abnormalities, including prominent nucleoli. *D.* Emperipolesis. Leukocytes have entered the cytoplasm of a cancer cell. (*A-D*: High magnification.)

Bronchial Brush Specimens

Bronchial brushing is of particular value in sampling small adenocarcinomas of the lung (Hattori et al, 1971). In wellsampled specimens, the tumor cells are more abundant than in a bronchial aspirate or wash. The cells often appear in **papillary clusters** (Fig. 20-12A), or in **sheets of large rounded or polygonal cells** (Fig. 20-12B). The latter may be mistaken for mesothelial cells but usually form glandular patterns and lack the intercellular “windows” of mesothelium. Suspect tumor cells in sheets are best studied by comparing their nuclei with those of clearly benign bronchial cells in the same smear. The brush specimens of **mucus-producing adenocarcinomas** may yield tumor cells with **large mucus vacuoles that displace the nucleus, superficially resembling goblet cells** (Fig. 20-12C). Some of the papillary adenocarcinomas of lung may have psammoma bodies, and on rare occasions, one may find **psammoma bodies** surrounded by tumor cells in a cytology specimen (Fig. 20-12D). Depending on fixation, the nuclei may be clear and vesicular or air-dried and pale staining, but they are provided with **readily visible and often prominent nucleoli**. In the uncommon small-cell variant of adenocarcinoma, the nuclei are about twice the size of nuclei of hyperplastic basal cells and must be differentiated from them and from the tumor cells of SSC (Fig. 20-13A).

Some **tumor cells may resemble normal ciliated bronchial cells**, but differ by their generally **larger size, greater nuclear/cytoplasmic ratio, the presence of prominent and sometimes multiple nucleoli**, and (most important) **the absence of cilia**. Ciliated cancer cells are very rare.

It was previously pointed out in reference to sputum cytology that the diagnosis of bronchogenic squamous carcinoma should *not* be made in the absence of single cancer cells. A contrary

situation applies in the interpretation of **brush specimens of bronchogenic adenocarcinoma**, wherein the identification of **cancer cell clusters is of major diagnostic importance**.

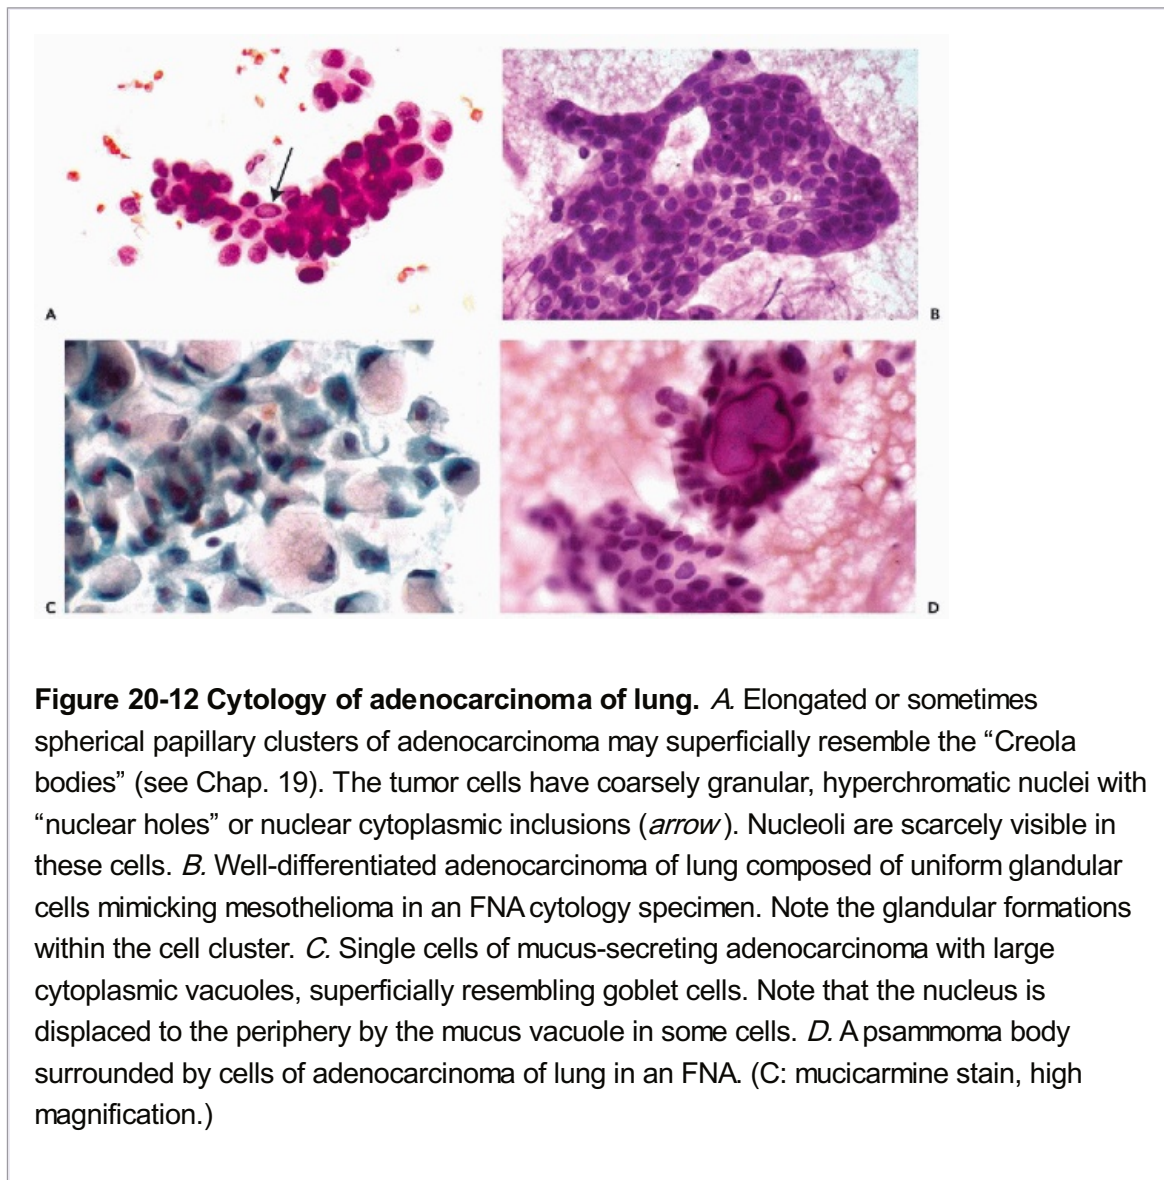

Percutaneous needle aspiration cytology is the same for all types of pulmonary adenocarcinoma and is discussed below.

Bronchioloalveolar Carcinoma (Terminal Bronchiolar Carcinoma)

The recognition and classification of bronchioloalveolar carcinoma (BAC) as a specific subtype of non-small-cell lung cancer has taken on new importance following recent advances in targeted, molecular-based chemotherapy. Mutations

P.663

in the tyrosine kinase domain of the epidermal growth factor receptor (EGFR) are believed to initiate a series of intracellular signaling reactions that promote cell survival and contribute to carcinogenesis. Two drugs designed to interface with tyrosine kinase signaling (Iressa and Tarceva) have had a dramatic response in patients with BAC, particularly nonsmokers. The drugs are ineffectual in other non-small-cell lung cancers (Ebright, 2002; Lynch, 2004; Zakowski, personal communication, Nov. 19, 2004).

Histology

These tumors arise in bronchiolar or alveolar epithelium of peripheral lung tissue and may present as a **localized mass or masses** in lung parenchyma similar to central adenocarcinoma (see Fig. 20-9A) or as a **diffuse pneumonic type** of infiltrating carcinoma that represents intrapulmonary spread (see Fig. 20-10C). In the **diffuse type** of lung cancer, there is **extensive replacement of large portions of the pulmonary parenchyma by adenocarcinoma**. The proliferating tumor cells are uniform and orderly in appearance and **utilize the alveolar framework for support so that at least initially, the basic architecture of the lung remains well preserved, so-called lepidic spread** (see Fig. 20-10D). Tumor cells often form papillary projections into the alveolar space. These diffusely spreading bronchioloalveolar carcinomas may be divided into two types (Manning et al, 1984): **type I, characterized by tall, mucus-producing cells with basal nuclei lining the tumor septa** (see Fig. 20-10D); and **type II, wherein the septa are lined by smaller, cuboidal cancer cells with more centrally located nuclei** (see below). The 1999 WHO classification of these tumors retained this division as **mucus-producing** and **non-mucus-producing** bronchioloalveolar carcinomas. Surfactant apoproteins can be demonstrated in the latter, consistent with origin in Clara cells and type II pneumocytes (Mizutani et al, 1988). A mixed form of these tumors has also been recognized. As the tumor progresses, there is invasion and destruction of lung parenchyma, and the proliferating tumor cells become more malignant in appearance and form solid tumor masses. As with the other non-small-cell lung cancers, survival depends on successful surgical resection and results are best for the small, localized tumors.

P.664

Figure 20-13 Bronchioloalveolar carcinoma, type II. *A.* Sputum showing a cohesive group of small tumor cells with scanty cytoplasm and uniform hyperchromatic nuclei. The nuclei are only 1.5 to 2.5 times the size of bronchial basal cell nuclei and may be mistaken for small-cell (oat cell) carcinoma (SCC), but do not have the other features of SCC (see Fig. 20-7). *B.* Sputum with a cluster of glandular cancer cells that have delicate chromatin, prominent nucleoli and scanty, pale-staining cytoplasm. *C.* Sputum: a cluster of disarranged, overlapping glandular cancer cells with variably sized nuclei and a moderate

amount of pale, eosinophilic cytoplasm. *D.* Bronchial brush specimen with loosely coherent cells of adenocarcinoma with uniform, round nuclei that are only slightly larger than the nuclei in the nearby benign bronchial cells. The tumor cells show delicate nuclear chromatin, prominent nucleoli, and very scanty, lightly stained cytoplasm.

Years ago, the well-differentiated (type I) tumors, made up of uniform, columnar, mucus-secreting cells growing along alveolar septa, were classified as **pulmonary adenomatosis**. Many of these patients died of respiratory failure without evidence of metastases, and there was a question about whether the tumors were malignant. This form of adenocarcinoma has striking morphologic similarity to a communicable viral disease of **sheep**, first observed in South Africa under the name *jaagsiekte* (the “driving disease” in Afrikaans, so called because the frantic, oxygen-deprived sheep break into a gallop just before death). The concept of “pulmonary adenomatosis” is now obsolete, as **all types of bronchioloalveolar carcinomas are capable of metastasis**.

Cytology

Sputum and Bronchial Secretions

Sputum is by far the best diagnostic medium for this group of tumors. **In nonmucus-producing type II tumors, the sputum contains variable numbers of well-demarcated, rounded, or papillary clusters of tumor cells.** Such clusters are composed of overlapping small, **round, or roughly cuboidal cancer cells with scanty clear or lightly stained cytoplasm and moderately hyperchromatic nuclei with one or two small nucleoli** (Fig. 20-13A-C). Small-cell adenocarcinoma (see Fig. 20-13A) may have to be differentiated from small-cell (oat cell) carcinoma, but cell groups of adenocarcinoma are tightly clustered, and the component cells lack the molding and necrosis so characteristic of SSC. As already noted, some of the papillary clusters of cancer cells may resemble and **must be distinguished from the so-called Creola bodies** (see below and Chap. 19). Other, loosely coherent cell clusters may be flat, composed of relatively uniform cells with usually distinct cell borders and finely textured nuclei with small nucleoli (Fig. 20-13D). **Isolated single cancer cells are few, and may be difficult to identify** in this tumor type. Thus, the diagnosis rests on identifying tumor cell clusters.

P.665

In the mucus-producing type I bronchioloalveolar carcinoma, characterized by tall columnar mucus-secreting cells (see Fig. 20-10D), the cytologic presentation is different. The sputum contains single recognizable malignant cells as well as cell clusters. The tumor cells are larger than those of type II carcinoma and have abundant mucus-producing clear cytoplasm (Fig. 20-14A). They have one or two finely textured nuclei with sharply defined nuclear membranes and visible or sometimes prominent nucleoli (Fig. 20-14B). Tumor cell clusters may be composed of overlapping cells or of flat coherent groups of cells with a glandular or acinar configuration (Fig. 20-14C). Columnar cancer cells are uncommon. Some may have a flat free cell border and mimic benign bronchial cells, but they do not have cilia or a terminal bar. We have seen only a single case of pulmonary adenocarcinoma with cilia on the surface of tumor cells (which were accompanied by conventional cancer cells), and it was clearly an exception to the very good rule that ciliated cells should not be considered malignant.

Bronchial Brush Specimens

The tumor cells in bronchial brush specimens are similar to those described above, except that the collection procedure results in formation of flat groups and strips. Figure 20-15A illustrates an example of bronchial brush cytology in type II bronchioloalveolar carcinoma. The cancer cells have relatively large nuclei, easily visible nucleoli, and a moderate amount of pale-staining cytoplasm. Some may have a columnar or cuboidal configuration. The smaller nuclei of benign bronchial cells that are present are useful for comparison. Figure 20-15B is an example of bronchioloalveolar carcinoma, type I. The cells are large with abundant transparent cytoplasm and spherical nuclei, some with nucleoli. The differential diagnosis must include metastatic mucin-secreting adenocarcinoma, including colonic carcinoma (see below). The tumor cells in **bronchial brush specimens** of bronchioloalveolar carcinoma **may mimic normal bronchial cells, but their presence in sheets of cells, absence of cilia and terminal bar, and their nuclear features identify them as adenocarcinoma.**

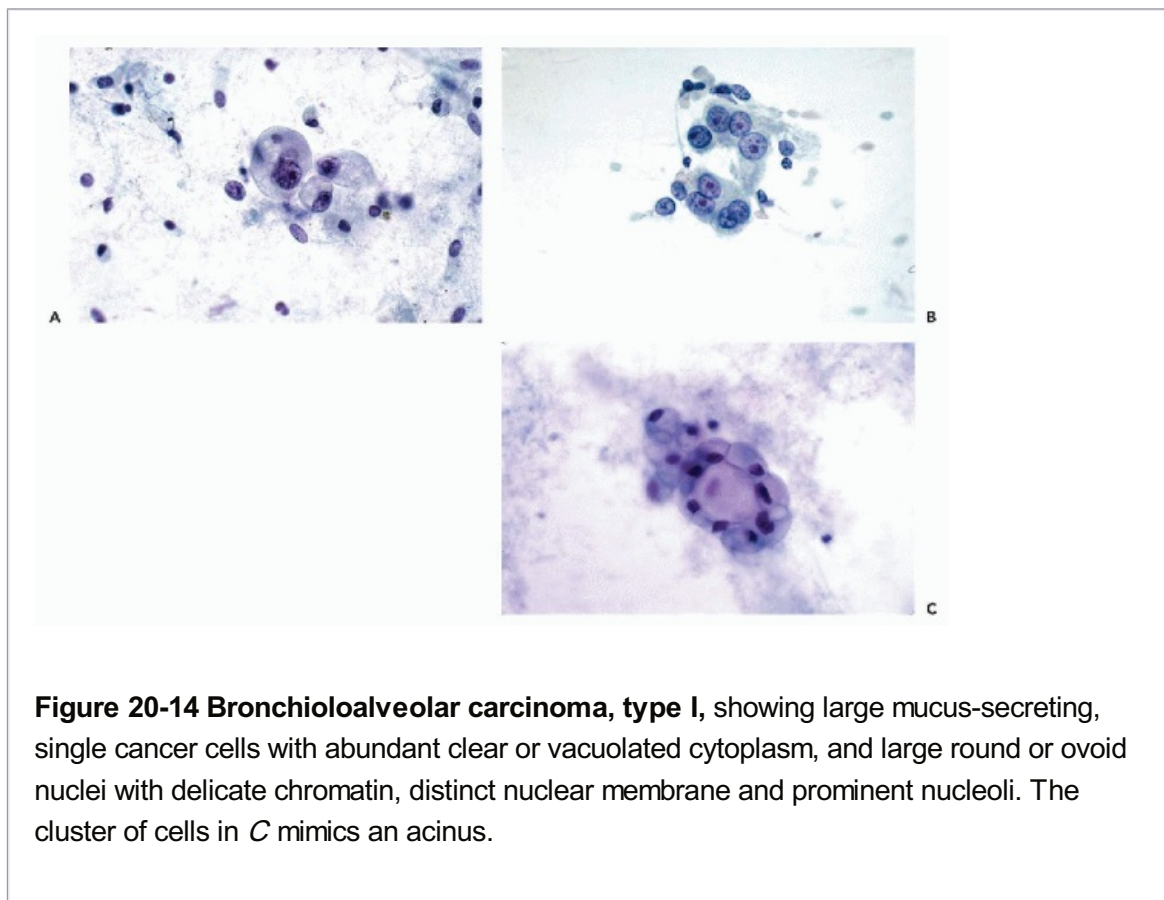

Figure 20-14 Bronchioloalveolar carcinoma, type I, showing large mucus-secreting, single cancer cells with abundant clear or vacuolated cytoplasm, and large round or ovoid nuclei with delicate chromatin, distinct nuclear membrane and prominent nucleoli. The cluster of cells in *C* mimics an acinus.

Percutaneous Fine Needle Aspirates

Bronchogenic adenocarcinoma is the most frequently seen primary tumor in percutaneous needle aspirates of the lung. **If the aspirate is performed well, there should be an abundance of tumor cells**, similar to the tumor cells illustrated above in bronchial brush specimens. One should be cautious of making a diagnosis based on a few isolated cells in a milieu of otherwise benign epithelial and inflammatory cells. As in other specimens, cytologic criteria for identification of the tumor type depend on the degree of differentiation: **gland-forming cancers are characterized by papillary, glandular, or rosette-like cell clusters and usually few single cuboidal or columnar cancer cells.** In some cases, the delicate cytoplasm of these glandular cancer cells may be damaged or lost, and the smear then contains **sheets or clusters of stripped**

nuclei with prominent nucleoli (Fig. 20-16A). Well-preserved cells may retain their columnar or cuboidal shape and form chains of cells (Fig. 20-16B) or gland-like patterns, not usually seen in undifferentiated large-cell carcinoma. The latter have denser staining, sharply defined polygonal or irregularly configured cytoplasm. In many instances, these two sometimes arbitrarily divided types of cancer cannot be differentiated.

Figure 20-15 Brush cytology of bronchioloalveolar carcinoma, type II (A) compared with type I (B). Note the larger, mucus-producing cancer cells in B.

Figure 20-16 FNAs of bronchioloalveolar carcinoma are similar to bronchial brush specimens but more cellular. A. Nuclei may be stripped of cytoplasm but retain their fine chromatin structure and prominent nucleoli. B. Cuboidal and columnar mucin-secreting cells of type I bronchioloalveolar carcinoma in linear and pseudoglandular arrangement. C. Single large cells of adenocarcinoma. Note the abnormal mitotic figure. D. Diff-Quik stain of a wet-fixed smear.

In the mucus-producing type I tumors, the cancer cells in FNA specimens tend to be larger and often of cuboidal or columnar configuration with abundant pale-staining

amphophilic cytoplasm that may be solid or

P.667

finely vacuolated (Fig. 20-16C,D), or may contain large mucus vacuoles. On occasion, single cancer cells **resembling macrophages** are found in aspirates of usually well-differentiated tumors. They are approximately oval or rounded large cells with abundant cytoplasm and large nuclei with coarse chromatin and visible or prominent nucleoli. They differ by their nuclear features from the macrophages that are invariably present, with which they can be compared, and they are almost always accompanied by other more obvious cancer cells. In methyl green pyronin, or Diff-Quik stain, cytoplasmic features may not be well demonstrated.

It must be stressed that it is not always possible to distinguish bronchioloalveolar carcinoma from other forms of bronchogenic adenocarcinoma, or from some metastatic tumors. Zakowski emphasizes the presentation in flat sheets of cells in imprint cytology, with irregular nuclei, nuclear grooves, and intranuclear cytoplasmic inclusions (personal communication). The tumor location and growth pattern as observed in the chest x-ray may be of help in distinguishing these tumor subtypes.

An unusual case of adenocarcinoma in which the needle aspiration cytology mimics mesothelium is illustrated in Figure 20-12B. This pseudomesotheliomatous lesion is of importance in the differential diagnosis of mesothelioma and is discussed in Chapter 26.

Sources of Diagnostic Error

The cytologic presentation of bronchioloalveolar and bronchogenic adenocarcinoma is similar, as noted above, and pitfalls in diagnosis of both tumor types may be discussed together.

In specimens of sputum, perhaps **the most difficult diagnostic problems** occur with the spherical **clusters of bronchial cells desquamated from hyperplastic bronchial mucosa in bronchiectasis, asthma, and other chronic respiratory disorders (Creola bodies)** (see Chap. 19). Such clusters differ from papillary clusters of cancer cells in that they are composed of generally uniform cells **without significant nuclear abnormalities** and particularly **without the prominent nucleoli** that characterize the cells of adenocarcinoma. Furthermore, in clusters from adenocarcinoma, the cells are often superimposed upon one another, whereas the benign cells from hyperplastic mucosal lesions are usually arranged in an orderly "flat" fashion. **Peripheral palisading of columnar cells, the presence of ciliated cells in the cluster, and the presence of identifiable goblet cells speak in favor of a benign condition.** Ultimately, the presence of clearly malignant cells is of critical diagnostic importance, whether they are found singly or in the clusters that characterize most specimens from adenocarcinomas.

Chemotherapeutic drugs, particularly **busulfan (Myleran)**, may induce bronchial cell abnormalities reminiscent of adenocarcinoma (see Chap. 19).

Also important in the differential diagnosis of adenocarcinoma is **hyperplasia of pneumocytes type II**, which occurs under various circumstances discussed at length in Chapter 19. The reactive pneumocytes are **large cells with prominent nucleoli** occurring singly and in small clusters. They may be seen in cytologic specimens from patients with a broad variety of benign lung disorders, including viral pneumonitis, adult respiratory distress syndrome (Stanley et al, 1992), chronic obstructive bronchiolitis, pulmonary infarction, and as an effect of treatment. Although atypical pneumocytes in those specimens may mimic the cells of adenocarcinoma, they are usually few in number. In cases of viral pneumonia or other febrile

illnesses, the cytologic abnormalities are transient and usually persist no longer than 2 or 3 weeks. Thus, repeat follow up examination may clarify the issue. Diffuse opacity of lung fields in the absence of a discrete tumor should serve as a warning that one may be dealing with a benign process.

Another potential source of cytologic error is the not uncommon presence of a few large bronchial cells with large nuclei (see Chap. 19). Such cells retain their columnar or cuboidal shape and, if they are ciliated or at least provided with a terminal plate, it is an indicator of benign atypia rather than cancer. Variations of nuclear size and abnormal nucleolar features that are diagnostic of adenocarcinoma are usually absent in an inflammatory or reactive atypia.

Objective and measurable cytomorphologic differences between reactive and neoplastic cells have been reported, but they are not entirely consistent (Zaman et al, 1997; Fiorella et al, 1998). A good rule to follow **when cytologic evidence of cancer is scanty is to take a conservative approach to the diagnosis.**

Differentiation of primary from metastatic adenocarcinoma of similar histologic type is clinically important but may prove impossible on cytologic grounds alone. If the past history of the patient or radiologic findings suggest the possibility of metastatic tumor, the burden of proof lies with the diagnosis of a new primary carcinoma of lung. Cytologic features that characterize the most common types of metastatic carcinomas in the lung are described later on in this chapter.

Precursor Lesions of Bronchogenic Adenocarcinoma

Histologic Observations

Friedrich (1939), Rössle (1943), and later Spencer (1985) pointed out the **association of peripheral lung cancers, mainly adenocarcinomas, with subpleural scars.** Alveolar interstitial fibrosis is almost always present at the margins of scarring in the lung, regardless of cause, and is associated with **reparative hyperplasia of bronchiolar and alveolar epithelial cells, a change that was thought to precede neoplasia in some cases.** The occurrence of bronchioloalveolar carcinoma in patients with scarring due to tuberculosis, cystic lung disease, or long-standing scleroderma (progressive systemic sclerosis) of the lung are cited as examples

P.668

of neoplasia arising in the epithelial hyperplasia that accompanies alveolar septal fibrosis (Meyer and Liebow, 1965; Talbott and Barrocas, 1980; Bielefeld, 1991; Paksoy et al, 1995). However, Shimosato et al (1982) have made a persuasive argument that **most scars associated with lung cancer are formed after the tumor develops,** and are caused by fibrosis of areas of tumor necrosis. Our own experience in the early lung cancer program at Memorial Sloan-Kettering Cancer Center, described below, is consistent with this view, since the vast majority of new lung cancers had no evidence of prior lung scar.

Meyer and Liebow (1965) described "atypical acinar proliferation" in lungs with honeycombing and interstitial fibrosis, and considered it to be a precursor of peripheral lung cancer. Later, Shimosato (1982) suggested that **atypical adenomatous hyperplasia (AAH) of bronchoalveolar epithelium may arise** in otherwise unremarkable lung tissue as a precursor of **peripheral adenocarcinomas of the lung.** The atypical is characterized by a layer of prominent cuboidal or columnar cells lining the terminal bronchioles and adjacent alveoli (Fig. 20-17), with or without slight interstitial fibrosis. The nuclei of these cells are often enlarged and somewhat hyperchromatic and may contain visible nucleoli, but rarely reach the level of

abnormality observed in adenocarcinoma. At the time of this writing (2004), there is consensus that the origin of most bronchioloalveolar carcinomas is from the **epithelium of terminal bronchioles and the lining of adjacent alveoli, and that AAH is the likely precursor lesion of at least some peripheral adenocarcinomas** (Shimosato et al, 1982; Noguchi et al, 1995).

The original suggestions by Montes et al (1977), Sidhu and Forrester (1977), and Jacques and Currie (1977) that **pneumocytes type II as well as Clara cells may participate in the pathogenesis of bronchioloalveolar carcinoma** have been amply confirmed by histochemistry, electron microscopy, and immunopathology (Bolen and Thorning, 1982; Espinoza et al, 1984; Linnoila et al, 1992). Both cell types have been demonstrated in the nonmucinous variant of bronchioloalveolar carcinomas (Singh et al, 1981; Dermer, 1982; Espinoza et al, 1984), although some tumors are preferentially composed of pneumocytes or of Clara cells (summary in Axiotis and Jennings, 1988). Ogata and Endo (1984) observed Clara-type cells in other forms of bronchogenic carcinoma.

Figure 20-17 Atypical adenomatous hyperplasia of alveolar epithelium, a putative precursor of bronchioloalveolar carcinoma.

It must be pointed out that **atypical adenomatous hyperplasia is similar to the hyperplasia of alveolar lining epithelium observed in certain inflammatory and chronic obstructive pulmonary diseases**, discussed in Chapter 19. In the examples of the benign reactive processes described, the **sputum contained abnormal pneumocytes type II with large nuclei and nucleoli, mimicking cells of adenocarcinoma, without evidence of progression to cancer**. Thus, the entity of AAH may be difficult, and in some cases impossible, to differentiate from atypical reactive hyperplasia and, like other precancerous lesions, it may not always progress to carcinoma.

Cytology

Once in a while, abnormal ciliated bronchial cells may be observed in bronchial washings or brushings from patients with lung cancer. **The affected ciliated cells have enlarged and hyperchromatic nuclei** and sometimes show an abnormally coarse nuclear chromatin pattern or prominent nucleoli. In an unpublished study, Koss found marked nuclear atypia of bronchial cells in bronchial washings and aspirates from 4 of 100 consecutive patients with lung cancer, and moderate atypia in 19 others. **Similar abnormalities of ciliated cells may be observed in isolated instances of cancer metastatic to the lung, but also in obstructive**

pulmonary disease, acute radiation reaction, and chemotherapy effect (see Chap. 19). However, **in a patient who has no other evidence of lung disease, a finding of marked bronchial cell atypia, although not diagnostic of cancer, should alert one to the possibility of an early occult adenocarcinoma.**

P.669

ADENOSQUAMOUS CARCINOMA

The term **adenosquamous carcinoma** is used to define bronchogenic carcinomas combining features of both epidermoid carcinoma and adenocarcinoma. While many undifferentiated large-cell carcinomas exhibit minor areas of glandular or squamous differentiation, the adenosquamous diagnosis is reserved for those **tumors composed predominantly of the two cell types**. Most show evidence of mucin secretion by special stains in addition to frank keratinization, and some have **minor components of undifferentiated large-cell or even SSC**. Their cytologic presentation varies depending on the histologic pattern.

Mucoepidermoid Carcinoma

The true mucoepidermoid carcinomas of lung are rare tumors, accounting for less than 0.2% of primary lung cancers (Colby et al, 1995). They arise in major bronchi or their branches, either from mucus glands in the bronchial wall or from the mucus-secreting surface epithelium, and form polypoid masses in the bronchial lumen.

Figure 20-18 Mucoepidermoid carcinoma of lung in a 61-year-old woman. *A* A tumor of bronchial mucus glands similar to the corresponding tumor of salivary gland origin composed of mucinsecreting glandular and epidermoid tumor cells. In bronchial brush specimens, the presence of both mucin-secreting (*B,C*) and epidermoid or squamous (*D*) cells may be observed.

Histology

As is suggested by their name, the mucoepidermoid carcinomas mimic similar tumors of salivary

gland origin (see Chap. 32), and are composed of a **mixture of differentiated and undifferentiated (intermediate) squamous cancer cells with interspersed mucinous glands or mucin-secreting single cells** (Fig. 20-18A). The **low-grade tumors** are localized, predominantly mucin-secreting, and have a generally good prognosis following resection. **High-grade tumors, usually characterized by a poorly differentiated squamous component with interspersed mucicarminophilic cells** are invasive, capable of metastasis, and resemble adenosquamous carcinomas of the lung, differing primarily in their **gross presentation as a polypoid intrabronchial mass**.

Cytology

We have seen brush cytology from a 61-year-old woman with this diagnosis. The dominant cancer cells were of a mucus-producing adenocarcinoma (Fig. 20-18B,C). There were only a few isolated, keratinized cancer cells (Fig. 20-18D). The patient was treated by surgery, but the tumor rapidly recurred with a pleural effusion. The diagnosis of

P.670

these uncommon tumors depends on **finding within the same specimen cells of squamous and adenocarcinoma**.

GIANT-CELL CARCINOMA (SPINDLE AND GIANT-CELL CARCINOMA)

These uncommon malignant tumors of lung constitute not more than 2% of all lung cancers. They may be considered a **subset of undifferentiated large-cell carcinomas**, and are characterized by the presence of **very large, often multinucleated, bizarre tumor giant cells** with equally **bizarre nuclei** and frequently **very large nucleoli** (Fig. 20-19). In the spindle and giant-cell variant, there is a sarcomatoid component of **spindly, elongated cancer cells resembling sarcoma** (Fig. 20-19C). Ozzello and Stout (1961) first documented the epithelial origin of these tumors, which was later confirmed by immunochemical expression of epithelial antigens (Fishback et al, 1994). Although the tumors have a bizarre appearance, common to all spindle and giant-cell tumors of various organs, their **prognosis appears to be about the same as that of other non-small-cell lung carcinomas** (Hellstrom and Fisher, 1963; Herman et al, 1966; Ginsberg et al, 1992).

Figure 20-19 Giant-cell carcinoma of lung. *A.* Histologic section showing bizarre tumor giant cells with large nuclei. *B.* Bronchial brush specimen in same case. *C, D.* Histologic section and bronchial brush cytology of a sarcomatoid giant-cell carcinoma. Compare the huge size of cancer cells with normal bronchial cells.

In sputum, bronchial aspirates, bronchial brush specimens, or needle aspiration cytology, the presence of isolated **very large, single or multinucleated tumor cells with huge bizarre nuclei is virtually diagnostic of this neoplasm** (Fig. 20-20B,D). **Smaller, undifferentiated malignant cells are almost always present as well.** Spindly tumor cells are rare. Although it has been suggested that these tumors may represent a bizarre variant of adenocarcinoma, we have not found cytologic evidence to support this in our material, nor have Broderick et al (1975) or Naib (1961). In one of our cases, the tumor was accompanied by a **squamous carcinoma in situ**, strongly suggesting that the tumor was of squamous derivation.

Differential Diagnosis

Spindle and giant-cell carcinomas of other organs (e.g., the thyroid, esophagus, uterine cervix) may metastasize to the lung, as do many **sarcomas**, any of which may shed cells identical with those described above. These are rare tumors, however, and it is usually obvious clinically that the lung lesion is a metastasis. Perhaps the most important differential diagnosis is the **effect of radiotherapy** on more common types of primary lung cancer. **Irradiation and sometimes chemotherapy** may produce huge distorted

P.671

tumor giant cells that in the absence of clinical data cannot be differentiated from giant-cell carcinoma.

SECOND PRIMARY LUNG CANCERS

Individuals who have had non-small-cell lung cancer and survived following resection are at increased risk of another lung cancer, which was estimated at about 2% per year by Pairolero et al (1984). Martini and Melamed (1975) reported a series of 50 patients with multiple primary lung cancers, 18 synchronous and 32 metachronous. In 31 patients, the second carcinoma was of the same histologic type, mostly squamous. In the remaining 19 patients, the histology was different. Similar observations were made by Broghamer et al (1985) who reported cytologic studies on 17 of 23 patients with second primary lung cancers. In 10 cases, cytologic diagnosis preceded histologic verification. Cytology is mandatory in monitoring patients after curative resection of lung cancer. It can present diagnostic difficulties in patients treated by adjuvant or postoperative irradiation.

PRECURSOR STAGES OF BRONCHOGENIC SQUAMOUS CARCINOMA

It is logical to assume that bronchogenic carcinomas, in common with other malignant epithelial tumors, are **preceded by a sequence of epithelial changes during malignant transformation before invasion**. Little is known about the histologic abnormalities occurring in the formative stages of **adenocarcinoma, although atypical adenomatous hyperplasia is a presumed precursor lesion (see above)**. Virtually nothing is known about the precursor stages of **SSC**. The best information is available for **squamous carcinoma** and the precursor lesion known as **squamous carcinoma in situ**.

Historical Overview

In 1935, a Finnish investigator, Lindberg, observed that squamous metaplasia is a frequent finding in the bronchi of patients with lung cancer. Subsequent histologic studies,

P.672

notably by Auerbach et al (1957) and by Nasiell (1966), supported this observation and squamous metaplasia was considered to be an important step in the genesis of bronchogenic squamous carcinoma. The possible mechanism of formation and frequency of occurrence of squamous metaplasia were discussed in Chapter 19.

Auerbach et al (1957, 1961) systematically mapped epithelial changes in the bronchial tree of cigarette smokers at autopsy, and found varying degrees of cytologic abnormality in patchy areas of the bronchial epithelium. However, even in the most severely affected bronchi, large areas of normal or nearly normal respiratory epithelium were present. There was no good explanation for the patchy distribution of epithelial abnormalities but, because the sites of bronchial division (bronchial spurs) were most frequently affected, it was thought that local variation in airflow might play a role in this phenomenon. The epithelial abnormalities were most frequent and most severe in patients who had invasive squamous carcinoma. Auerbach's work suggested that histologically identifiable bronchial epithelial abnormalities precede the development of epidermoid carcinoma. **It was generally assumed that the initial carcinogenic event was squamous metaplasia that progressed to atypical metaplasia.**

In the most severe of these epithelial changes, the entire thickness of the epithelium was occupied by abnormal cells resembling the cells of invasive carcinoma, and this lesion was termed carcinoma in situ. A somewhat similar sequence of events was observed in experimental carcinogenesis of the trachea in hamsters (Schreiber et al, 1974; McDowell and Trump, 1983).

Saccomanno et al (1974) described their experience with long-term cytologic studies of a large population of uranium miners in comparison with cigarette smokers and nonsmokers. They proposed a sequence of epithelial events in the development of bronchogenic epidermoid carcinoma, which is summarized in Table 20-3.

On the basis of cytologic data, Saccomanno et al (1974) recorded the time of transition from moderate cytologic atypia to invasive epidermoid carcinoma at 4.8 years (ranging from 0.3 to 9 years) and from carcinoma in situ to invasive epidermoid carcinoma at 2.5 years (ranging from 0.5 to 6.2 years). Updated figures, based on cytologic and clinical observation of a larger group of patients and kindly provided by Dr. Saccomanno in 1977, suggest somewhat longer average times of transition: 9.4 years for transition from moderate atypia to invasive carcinoma and 3.2 years for transition from carcinoma in situ to invasive carcinoma. A similar sequence had been suggested previously by Koprowska et al (1965) and by Nasiell (1966).

Invasive squamous carcinoma	

The concept of squamous metaplasia as a precursor lesion of bronchogenic carcinoma was subsequently challenged by Melamed et al (1977). In a detailed histologic study of the resected lobectomy specimens from patients with in situ or incipient invasive epidermoid carcinoma of lung, they found **no transition from squamous metaplasia or basal hyperplasia to carcinoma.** On the contrary, **the carcinomas seemed to arise de novo from transformed basal (reserve) cells of the bronchial epithelium.** Further, squamous metaplasia, which is a common finding in the absence of carcinoma, was seen predominantly in the mainstem and lobar bronchi, whereas the earliest in situ and focally invasive carcinomas were found to arise in more distal segmental and subsegmental bronchi. Melamed et al concluded that **neoplastic transformation of bronchial epithelium induced by respired carcinogens (such as tobacco smoke) proceeds independently of squamous metaplasia and basal hyperplasia.** The latter were believed to be a nonspecific reaction to the irritating smoke. These views received support from the observations of an **abrupt transition between normal respiratory epithelium and carcinoma in situ without intervening squamous metaplasia, and from the location of squamous metaplasia commonly in mainstem and lobar bronchi, whereas in situ carcinoma was most commonly found more distally in subsegmental bronchi** (Fig. 20-21). It is also known from Auerbach's work that the frequency of atypical metaplasias in the bronchial tree of smokers vastly exceeds the expected number of invasive bronchogenic cancers. Hence, it is reasonable to assume that few of these lesions progress to carcinoma and the outcome in any given case is unpredictable. The readers should be cautioned, however, that many pathologists still regard squamous metaplasia to be an essential precursor of squamous lung cancer.

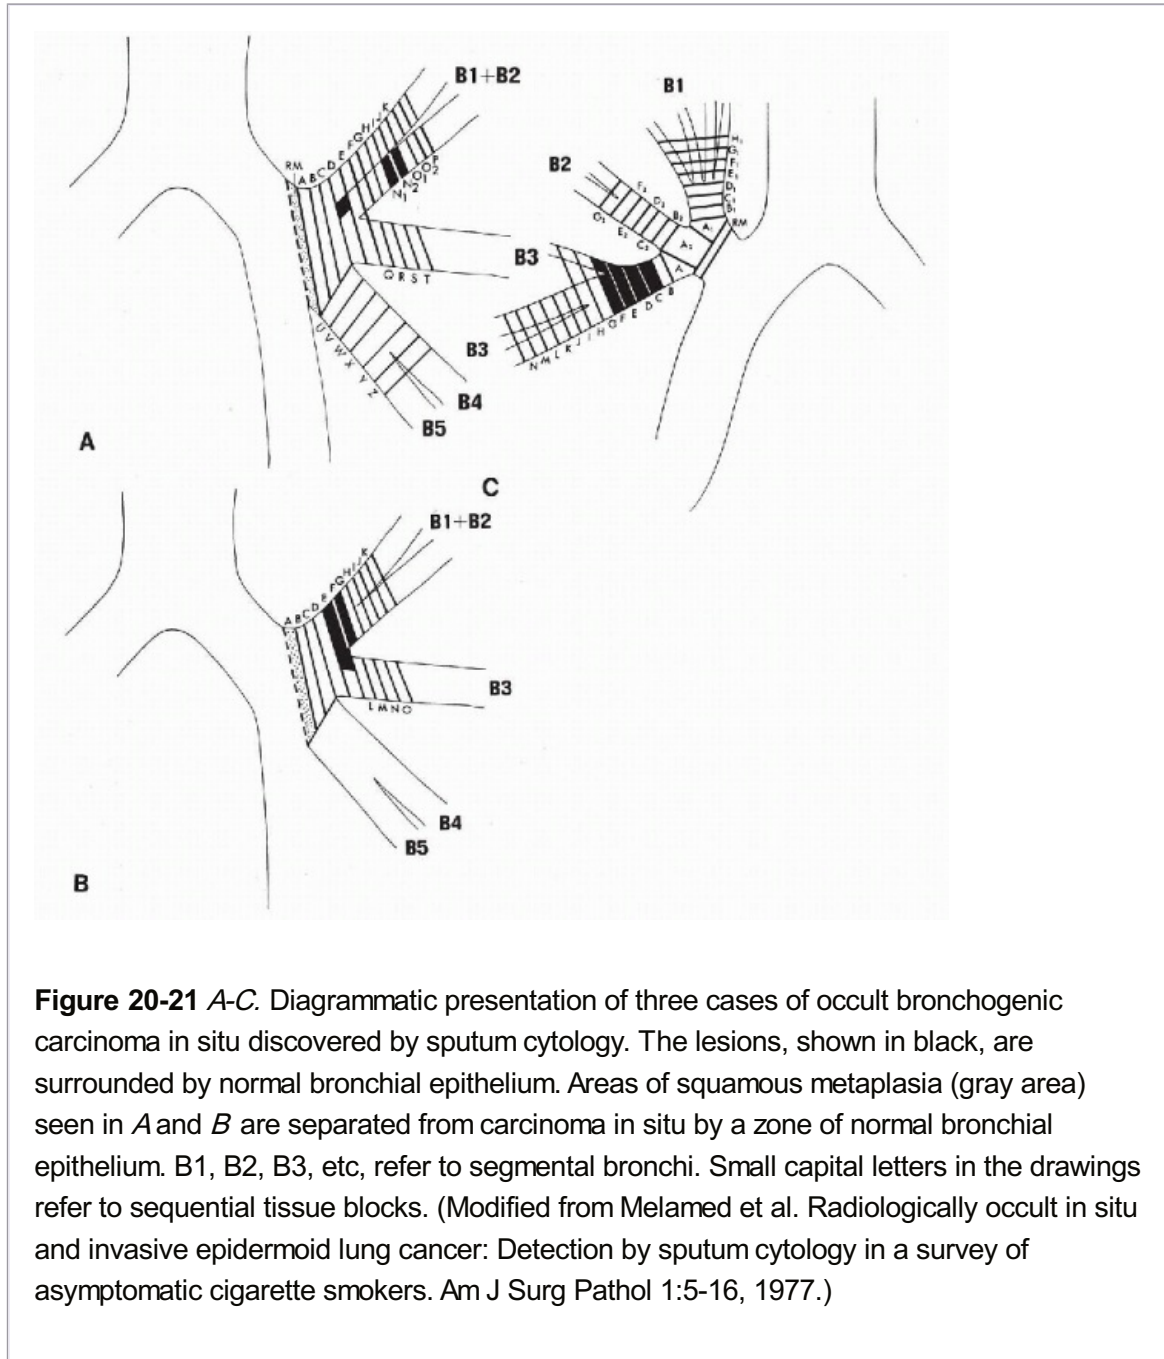

Despite differing views on the pathogenesis of lung cancer, most pathologists are in agreement on the criteria for diagnosis of **in situ carcinoma** of the bronchus, which may be well or poorly differentiated. Some pathologists prefer the term **dysplasia** for the well-differentiated carcinomas in situ. The cytology of these lesions is discussed below.

The natural history of bronchogenic squamous carcinoma in situ, the probability of progression, and the time required for progression to invasive cancer are not yet known. Certainly, not all atypical squamous metaplasias will progress to in situ or invasive cancer, and there are only a very few patients with biopsy-confirmed carcinoma in situ who have been followed without treatment (because of medical

P.673

contraindications or refusal of surgery). In one well-documented case seen by one of us (M.R.M.), and in another seen by Woolner at the Mayo Clinic (personal communication), the time of progression from in situ to invasive carcinoma was at least 5 years. In two other cases seen by one of us (LGK), time intervals of 4 to 6 years elapsed from cytologic diagnosis of bronchogenic carcinoma until clinical cancer developed. Nasiell et al (1977) reported time intervals of 8 to 9 years from *cytologic* diagnosis of bronchogenic carcinoma in situ to the clinical diagnosis of cancer. One of his patients with documented bronchogenic carcinoma in situ was followed for 13 years without clinical evidence of invasive cancer. These anecdotal experiences suggested a **transit time of 5 to 10 years for progression of in situ to invasive squamous carcinoma.** In a mathematical model based on data from the Memorial Sloan-Kettering early lung cancer study, Flehinger and Kimmel (1987) and Flehinger et al (1988) estimated a **minimum of 4 years duration for the early stage of lung cancer.** Thus, there appears to be ample opportunity for early detection and treatment of at least some lung cancers (see below). There is still very limited experience with treatment of carcinoma in situ by

locally ablative photodynamic therapies (Cortese and Edell, 1993). With few exceptions, even very limited foci of in situ or microinvasive carcinoma require lobectomy. Further, **eradication of in situ or invasive carcinoma in one bronchus does not exclude the possibility of additional carcinomas occurring in other areas of the bronchial tree** (see above, second primary lung cancers). Thus, the management of bronchogenic squamous carcinoma in situ is still a dilemma, and likely to remain so for many years.

P.675

Cytology of Sputum

As noted, Saccomanno proposed some of the most detailed diagnostic criteria for cytologic identification of the presumed precursors of bronchogenic epidermoid carcinoma and described

their progression to invasive carcinoma. His work was primarily with uranium miners in western Colorado who were exposed to naturally occurring radon gas, but were also cigarette smokers. Saccomanno's views received support from cytologic studies of experimental carcinoma of the respiratory tract in hamsters, conducted by Schreiber et al (1974) (Fig. 20-22). He considered squamous metaplasia of the bronchial epithelium to be an important link in the chain of events.

Simple Squamous Metaplasia

In the absence of nuclear atypia, squamous metaplasia cannot be considered a precancerous lesion. As discussed in Chapter 19, it is a common finding, particularly among individuals exposed to irritating dusts or gases, or subject to recurrent respiratory tract infections. The cytologic presentation of simple squamous metaplasia without atypia was described and illustrated in Chapter 19.

Squamous Metaplasia With Atypia

In contrast to simple squamous metaplasia, a finding of squamous metaplasia with nuclear abnormalities should raise the possibility of a precancerous lesion. Atypical squamous metaplasia may accompany squamous carcinoma in situ (see below), or in some cases of apparent progression to invasive carcinoma, **it may already represent carcinoma in situ.** In other instances, there is regression of atypical squamous metaplasia, or at least no apparent progression of the lesion. Risse et al (1988) followed a group of 46 patients with a diagnosis of "severe dysplasia" by sputum cytology, and 21 eventually developed lung cancer while 25 did not.

Cytology

Squamous metaplasia is manifested in sputum and bronchial specimens by **loosely structured clusters of small squamous cells with variably sized atypical nuclei** (Fig. 20-23). **The clusters have a mosaic pattern and one straight edge, a configuration suggesting origin from the surface of the bronchial mucosa** (see Chap. 19). **The distinction between**

markedly atypical squamous metaplasia and carcinoma in situ often is subtle, and a matter of judgment. The presence of single, well-differentiated abnormal cells (with or without similar cells in clusters) points toward the diagnosis of squamous carcinoma in situ; the cells derived from atypical squamous metaplasia are less well differentiated and more likely to remain in coherent groups.

As a practical matter, **all patients with atypical squamous cells in sputum or bronchial samples should be carefully followed.** Repeat examinations of additional cytology specimens will be necessary to ensure that sampling is adequate, and they must be diligently searched for single cancer cells. In some instances, **a very few single malignant cells have been identified in specimens several years before bronchogenic carcinoma was diagnosed.** It is not known whether the exfoliated cells came from a precursor lesion or an occult and indolent invasive carcinoma. Several examples of markedly atypical squamous cells interpreted as atypical metaplasia preceding carcinoma in situ were reported from the Cooperative Early Lung Cancer study. In our own experience in that same study, however, **the cancer cells appeared abruptly in the sputum of patients without prior significant atypia.**

P.676

Differential Diagnosis

There are many conditions that may mimic **atypical squamous metaplasia**. These include small squamous cells from the deep layers of buccal epithelium and larynx, frequently present in inflammatory or ulcerative processes (see Chap. 21), "Pap cells" from the larynx (see Chap. 19), tracheitis sicca associated with tracheostomy (see Chap. 19), and nonspecific inflammatory changes occurring in metaplastic bronchial cells. Atypical metaplastic cells may also be confused with the **atypical squamous cells of pemphigus** involving the upper respiratory tract (see Chap. 21); with nonspecific cell abnormalities observed in **viral pneumonia**; with specific viral infections, mainly **herpes simplex**; and with **drug-induced changes** (see Chap. 19).

Potential Markers of Progression of Atypical Metaplasia to Cancer

There are still too few follow-up studies of atypical metaplastic lesions to predict their behavior or even to define them reliably from one laboratory to another. This presents a practical problem in management of the individual patient and also in evaluating studies of drugs intended to prevent progression or reverse presumed precancerous lesions (Melamed and Flehinger, 1993). DNA aneuploidy has been reported in some cases of atypical squamous metaplasia (Nasiell et al, 1978; Hirano et al, 1994), and may be a marker of progression.

Figure 20-24 Squamous carcinoma in situ with microinvasion. *A.* Sputum cytology showing well-differentiated, single squamous cancer cell with opaque eosinophilic cytoplasm and hyperchromatic, irregular enlarged nucleus. *B.* Gross appearance of the resected lobe of lung showing thickened mucosa with loss of rugal folds in the segmental bronchus with carcinoma in situ. *C, D.* Histologic sections showing carcinoma in situ. *D.* Microinvasive carcinoma. (From Melamed MR, Koss LG, Clifton EE. Roentgenologically occult lung cancer, diagnosed by cytology. Report of 12 cases. Cancer 16: 1537-1551, 1963.)

Tockman et al (1997) reported **overexpression of the heterogeneous nuclear riboprotein (hnRNP) A2/B1** in archival sputum specimens of patients with atypical squamous metaplasia progressing to squamous carcinoma in situ. This finding was supported by a prospective study of Chinese miners at high risk of lung cancer (Qiao et al, 1997), and by a study of bronchial lavage specimens (Fielding et al, 1999). Expression of **p53 and K-ras point mutations** in sputum cells also may precede morphologic diagnosis of lung cancer by some months and perhaps even years (Mao et al, 1994). However, the sensitivity of these tests is low, and their applicability to the detection of small peripheral lung cancers has yet to be documented (Gazdar and Minna, 1999).

Cytology of Squamous Carcinoma In Situ

In sputum specimens from many of our own cases of squamous carcinoma in situ, and from specimens graciously

P.677

loaned to us by others, ^{*} **the most consistent finding has been the presence of well-differentiated squamous cells with the nuclear abnormalities of cancer occurring usually singly or, uncommonly, in small clusters** (Figs. 20-24, 20-25 and 20-26). They are similar to the **dyskaryotic squamous cells of keratinizing squamous carcinoma in situ of uterine cervix** (see Chap. 11). Similar cells may be seen in squamous carcinomas in situ of other organs, such as the esophagus and larynx (see Chaps. 21 and 24).

Figure 20-25 Carcinoma in situ with microinvasive carcinoma. A1,A2. Sputum with single well-differentiated squamous cancer cells. Same patient with papillary carcinoma in situ at the bifurcation of a segmental bronchus (B) and adjacent flat carcinoma in situ with microinvasion (C). (From Melamed MR, Zaman MB, Flehinger BJ, Martini N. Radiologically occult in situ and incipient invasive epidermoid lung cancer. Detection by sputum cytology in a survey of asymptomatic cigarette smokers. Am J Surg Pathol 1:5-16, 1977.)

The characteristic cells are typically large, superficial squamous cells with moderately abundant predominantly eosinophilic, but occasionally basophilic cytoplasm. They are smoothly contoured; the bizarre cell forms sometimes seen in invasive squamous carcinoma are uncommon. **Nuclei are hyperchromatic, irregular, and enlarged in proportion to the surrounding cytoplasm**, resulting in a higher-than-normal nucleocytoplasmic ratio. As discussed above, the differential diagnosis between markedly atypical squamous metaplasia ("grave" atypia of Dr. John Frost) and epidermoid carcinoma in situ is a matter of judgment. In case of doubt, further cytologic and clinical studies are indicated.

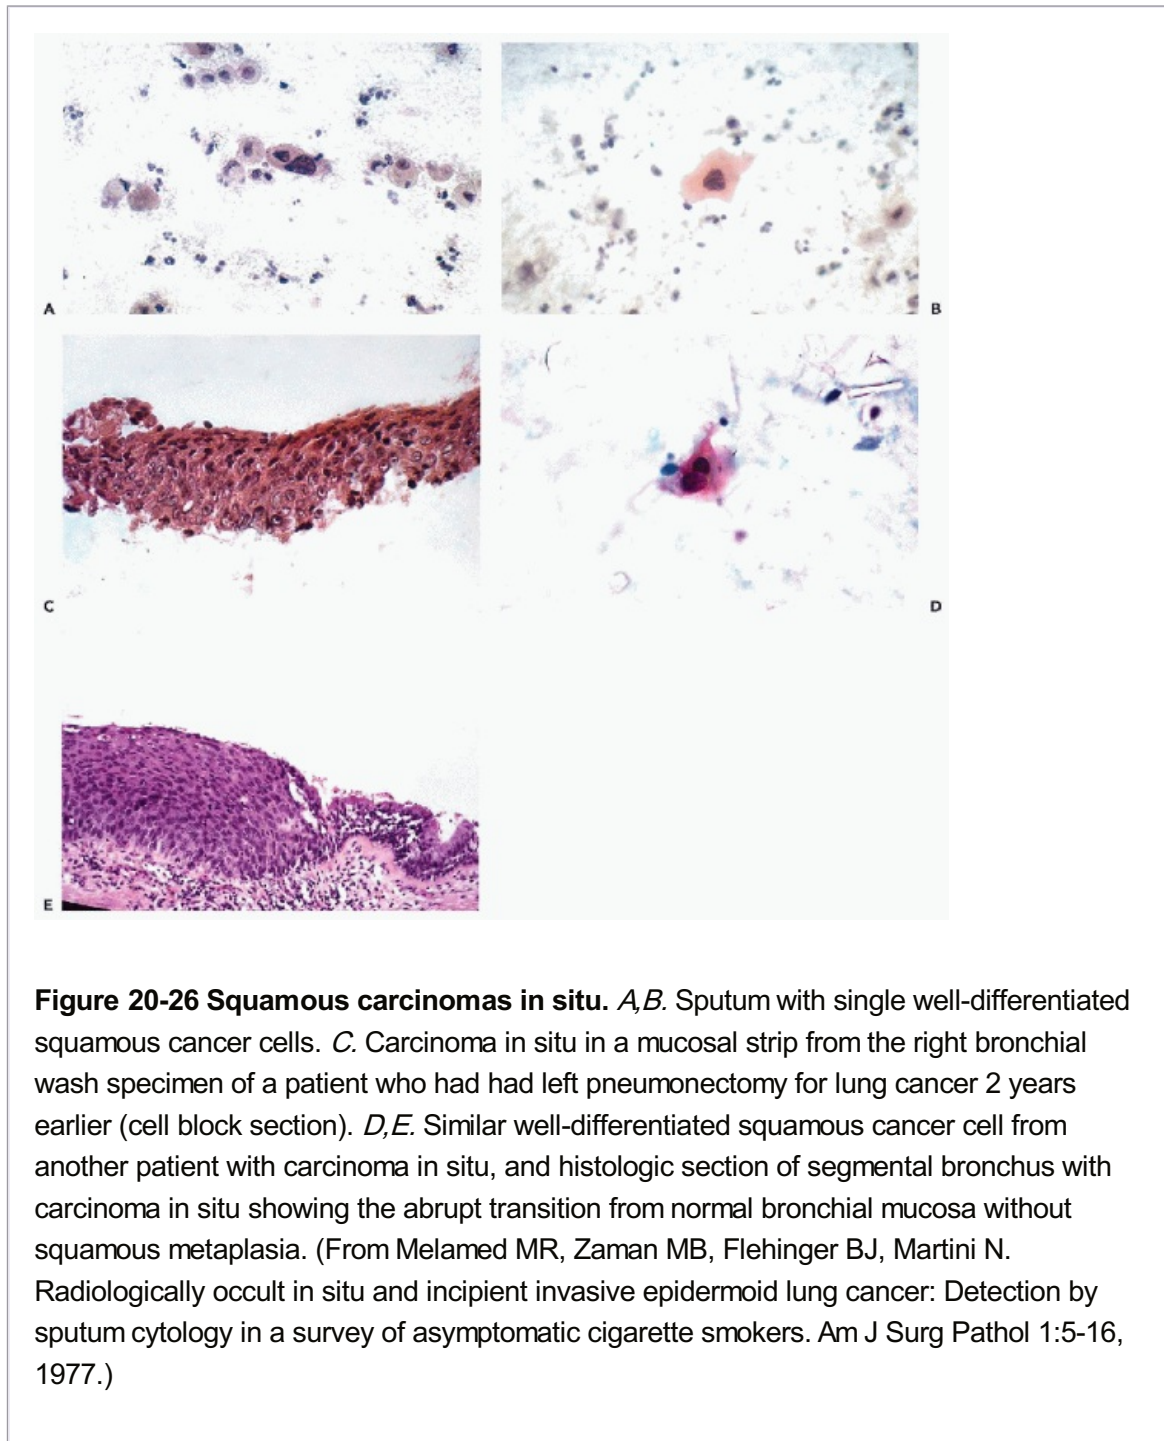

In **bronchial brush specimens, the abnormal squamous cells often form clusters and groups as well as single cells**. The cell groups are made up primarily of **superficial squamous cells, as in sputum, with cytoplasm that is often eosinophilic and sometimes frankly keratinized. Nuclei are significantly enlarged and usually coarsely textured, hyperchromatic, and irregular**. The break-up of the clusters and the presence of single cells, if any, speak in favor of fully developed carcinoma in situ. Detached fragments of epidermoid carcinoma in situ may occasionally be dislodged in a bronchial brush or wash specimen, and recognized in cell block preparations (Fig. 20-26C). Such rare events suggest that carcinoma in situ is more readily detached from the surface of the bronchus than is normal bronchial epithelium. Similar observations have been made for carcinomas in situ of the uterine cervix and the bladder (see Chaps. 11 and 23).

One of the features of carcinoma in situ is the failure to differentiate normally, as is seen, for example, in the lack

P.678

of cilia (Fig. 20-27). In more advanced invasive carcinomas, the cellular and nuclear

abnormalities are generally more marked, an observation confirmed by us and others (Tao et al, 1982), but **whether cells derived from squamous carcinoma in situ can be distinguished from cells of early invasive squamous carcinoma is still a matter of debate**. Erozan et al (1979) reported measurable differences between the cells of carcinoma in situ versus microinvasive and fully invasive cancer. Greenberg et al (1987), using sophisticated image analysis methods, also concluded that there were measurable differences between cells from reversible atypias, carcinoma in situ, and invasive cancer. In our view, the number of cases of in situ and microfocally invasive squamous lung cancer is still too low to draw firm conclusions.

Clinical Approach to Patients With Cancer Cells in Sputum in the Absence of Radiologic Abnormalities

A diagnosis of carcinoma by sputum cytology in the absence of localizing radiologic

findings must be confirmed on at least two separate specimens on two different days to rule out laboratory error. The diagnosis and treatment of such cases should then be governed by the following principles:

Once the cytologic diagnosis of cancer has been established, **a thorough examination of the buccal cavity, nasopharynx, larynx, etc., must be undertaken to rule out a possible source of cancer cells from the upper respiratory tract.**

P.679

Figure 20-27 Scanning electron micrograph of squamous carcinoma in situ of bronchus. *A.* Normal bronchus showing surface cilia. *B.* Carcinoma in situ at the margin with adjacent bronchial mucosa showing short microvilli replacing cilia. (Courtesy of Dr. Patricia Saigo.)

If the above procedures are negative, a thorough investigation of the bronchial tree is indicated. Fiberoptic bronchoscopy, preferably with videotape recording, is mandatory, and may have to be repeated if the source of the cancer cells is not found. Localized roughening and redness of the bronchial mucosa, and loss of the normal rugal folds, especially at a bronchial bifurcation or spur, may be the only visible evidence of squamous carcinoma in situ or microinvasive squamous carcinomas.

Even in the presence of a suspicious mucosal lesion, but particularly in the absence of a visible abnormality, **systematic bronchial brushing should be carried out**, and separately labeled specimens must be obtained from each lobar, segmental, and subsegmental bronchus.

Bronchial brushing samples and biopsies from tertiary and sometimes quaternary bronchi are technically feasible, and have been successful in confirming and localizing occult carcinomas.

We have never seen a case of confirmed positive sputum cytology in which fiberoptic bronchoscopy in skilled hands failed to localize the malignant lesion.

Under no circumstances should the patient be explored surgically before the source of the cancer cells has been localized and the surgical procedure defined in advance.

Carcinoma in situ and related lesions of the bronchus cannot be visualized or palpated at thoracotomy, and surgery will fail if it is undertaken before establishing the exact site of the lesion. In such a case, a renewed attempt at localization in the future will be made more difficult by the operative procedure, which will only delay definitive treatment, as happened to two of the

first patients we encountered.

A patient with positive sputum cytology may have a radiographically visible lesion that is benign and unrelated to an early, occult cancer located elsewhere in the bronchial tree. This was observed in two of our early patients, one with bronchiectases, and another with a Ghon tubercle. In the latter case, thoracotomy and resection of the radiologically visible lesion delayed definitive treatment and was followed by invasive carcinoma with a fatal outcome. If thoracotomy is undertaken on the assumption that a radiologic lesion is the source of the cancer cells in sputum, frozen section confirmation should be obtained for confirmation at the time of surgery.

PROGRAMS FOR DETECTION OF OCCULT BRONCHOGENIC CARCINOMA

History

The concept that early detection of lung cancer might lower mortality from that disease was first tested in the Philadelphia Pulmonary Neoplasm Research Project (Boucot et al, 1970; Weiss et al, 1982), the North West London study (Brett, 1969) and the South London Cancer Study (Nash et al, 1968). These surveys were based on photofluorogram chest x-rays used in mass surveys to detect tuberculosis and were not suited for detection of early lung cancer. Although they were successful in finding some unsuspected advanced cancer cases, the surveys failed to show that they could lower the mortality of lung cancer. **Cytology has played a key role in all subsequent efforts to detect early occult lung cancer.**

In 1951, Papanicolaou and Koprowska reported the **first documented case of radiographically occult carcinoma in situ of the bronchus diagnosed by cytology**, thus offering promise of a new technique for detection of preinvasive, potentially curable lung cancer. The first application of this procedure in a cancer detection survey of cigarette smokers was between 1959 and 1961 in New York City. Of 643

P.680

cigarette-smoking men aged 40 and over, two were found with occult carcinoma (see Fig. 20-24).

A number of reports of single and small groups of patients with radiologically occult carcinoma detected by sputum cytology were subsequently published (Lerner et al, 1961; Melamed et al, 1963; Holman and Okinaka, 1964; Pearson and Thompson, 1966; Lilienfeld et al, 1966; Woolner et al, 1966; Grzybowski and Coy, 1970; Woolner et al, 1970; Marsh et al, 1972; Martini et al, 1974). These reports, and the introduction of fiberoptic bronchoscopy to localize occult carcinomas discovered by sputum cytology, led to a large multicenter evaluation of sputum cytology as a lung cancer detection technique.

Early Lung Cancer Detection Studies Sponsored by the National Cancer Institute

Between 1972 and 1974, three major screening programs were initiated, sponsored by the National Cancer Institute under the direction of Dr. Nathaniel Berlin. They were designed to evaluate sputum cytology as an adjunct to the chest x-ray for lung cancer detection. The goal was to determine whether systematic, periodic examinations of sputum cytology, supplementing the chest x-ray, could lead to a significant reduction in the death rate from lung cancer in a selected population at high risk. The Johns Hopkins Medical Institutions, the Mayo Clinic, and the Memorial Hospital for Cancer were the participating institutions. A total of 31,360

asymptomatic male cigarette smokers, aged 45 or older, were recruited by the three groups into a study that continued for 5 to 8 years, until November, 1982, with up to 2 years of additional follow-up. Details of the study design have been published in a *Manual of Procedures* available from the National Cancer Institute (NIH publication no. 79-1972).

There were some differences among the three institutions. The men in the Hopkins and Memorial studies were recruited from the general populations of Baltimore and New York City, respectively, and randomly divided into a study group, offered annual chest x-rays (full size PA and lateral) and sputum cytology every 4 months, or into a control group that was offered the annual chest x-ray only. The Mayo population was recruited from their outpatient clinic, and excluded men with any suspicion of lung cancer on initial examination. All had chest x-rays and sputum cytology on entry and those without evidence of lung cancer were assigned to a "close surveillance" group that was offered x-ray and sputum cytology every 4 months, or to a "control" group that was advised initially but not reminded to seek periodic chest x-rays.

Prevalence Data

The lung cancer cases that have accumulated in the study population and are discovered in the initial screening examination are defined as prevalence cases. They include indolent cancers that may have been present for months or years.

In the initial (prevalence) screening, there were 160 patients with lung cancer detected among the 21,127 men who had dual screening with both sputum cytology and chest x-ray (0.75%); 93 cancers were detected by x-ray only, 37 by cytology only, and 30 by both techniques (Fontana et al, 1984; Frost et al, 1984; Flehinger et al, 1984; summary in Berlin et al, 1984). **Sputum cytology was useful almost exclusively for detection of squamous carcinomas, especially those located in subsegmental and larger central bronchi.** Most of the 93 lung cancers detected by x-ray only were adenocarcinomas or undifferentiated large-cell carcinomas; almost all of the peripheral adenocarcinomas were found by x-ray. Nearly half of the cancers detected by x-ray alone were stage I, and more than 80% of the cancers detected by cytology alone were stage I, that is, localized and potentially curable by resection. The 5-year survival rate for the patients with resected stage I lung cancer was 75% to 80%; and the 10-year survival in this study was 65%, which should be compared with the expected 12% 5-year survival rate for lung cancer nationally. These data emphasize the importance of screening asymptomatic individuals at high risk of lung cancer if one is to identify the disease in an early and curable stage.

Incidence Data

New lung cancers that developed after the initial screening are referred to as incident cases. They were observed during the year following the initial or subsequent negative annual examination and provide information on the rate of development of lung cancer. The most detailed incidence data come from the Memorial Hospital study in New York (Melamed et al, 1984; Melamed and Flehinger, 1987; Melamed, 2000), but are not significantly different from the other two institutions.

Of the 10,040 men recruited into the program in New York City, a total of 354 developed lung cancer, of which 293 were diagnosed during the screening period of 5 to 8 years and 61 during the postscreening follow-up period. Fifty-three men had lung cancer detected on the initial screening examination (prevalence = 0.5%), and 137 were detected by subsequent repeat screenings. Thus, 190 of 293 lung cancers diagnosed during the screening period (65%) were

detected by screening. The remaining 103 patients had lung cancer detected clinically because of symptoms or radiologic findings between scheduled screening examinations (interval cases). Not surprisingly, **over half of the rapidly growing small-cell (oat cell) carcinomas (12 of 21) were interval cases, diagnosed clinically because of symptoms.** As in the prevalence study, most of the lung cancers found by cytology were squamous carcinomas, and most of those found by x-ray were adenocarcinomas (Tables 20-4, 20-5 and 20-6). **Sixty-one additional cases were diagnosed clinically during the 2 years of follow-up after screening was discontinued, mostly in symptomatic patients who had advanced disease.**

The patients in this study with lung cancer diagnosed as a result of symptoms had an estimated 13% survival at 7 years, which is comparable to the estimated overall survival of 13% at 5 years for lung cancer throughout the US. Thus, for all practical purposes, **symptomatic lung cancer is late lung cancer, and the cure rates are dismal.**

Conclusions From the Early Lung Cancer Study

As mentioned in the opening pages of this chapter, there is good evidence that some early stage lung cancers detected by screening have high resectability and survival rates but, so far, there is no convincing statistical proof that screening lowers death rates from lung cancer (Fontana, 2000; Kubik, 2000). If this seems paradoxical, it has been suggested that some lung cancers discovered by screening are indolent and would never have progressed to cause illness and death (Black, 2000; Parkin and Moss, 2000). However, there is no persuasive evidence that this theory is correct. Thus, Flehinger et al (1992) reported 5-year survival of only 0% to 8% for untreated stage I lung cancer patients with adenoand large-cell carcinoma,

whereas 5-year survival ranged from 52% to 62% for men with the same tumor types and the same stage who were treated by surgery. Similarly, the higher death rates from lung cancer in black, compared to white, patients can be explained by lower rates of surgical treatment (Bach et al, 1999).

It is now virtually impossible to do a randomized study of lung cancer screening that denies chest x-rays to high-risk individuals. In the absence of such a study, it has become impossible to demonstrate that screening lowers the death rate from lung cancer (recently reviewed by Patz et al, 2000). In a mathematical model of the progression kinetics of lung cancer developed by Flehinger and Kimmel (1987, 1988) from data collected in the NCI study of lung cancer screening described above, it was concluded that annual screening could reduce lung cancer deaths by up to 18%.

Pending future developments in the new lung cancer screening programs based on spiral CT and summarized below, **the American Cancer Society recommends that physicians should decide for each individual patient whether the risk of lung cancer is sufficient to warrant periodic radiologic examination of the chest and cytologic investigation of any suspect lesion. The following categories of patients should receive special attention:**

- **Long-term cigarette smokers** over 55 years of age
- **Any adult with a history of persistent cough**, with or without hemoptysis
- **Any patient with recurrent pneumonia**, obstructive lung disease, or a localized pathologic process in the lung
- **Any patient with persisting or unexplained radiographic abnormalities**, whether or not considered benign
- **Industrial workers or others exposed to pulmonary carcinogens**, and particularly asbestos or radioisotopes (uranium mining)

Lung Cancer Screening Based on Spiral (Helical) Computed Tomography

Recent technical advances in CT (helical or spiral CT) have greatly shortened exposure times and significantly reduced irradiation to patients. Screening examinations of the chest now take 20 seconds or less and require no contrast medium (Kaneko et al, 1996; Sone et al, 1998; Nitta et al, 1999). This technique is now being applied to lung cancer detection in a number of programs, one of which is the "Early Lung Cancer Action Project" (ELCAP).

The ELCAP project, which now encompasses several institutions in the US and abroad, has undertaken a program of annual screening of asymptomatic patients at various degrees of risk for lung cancer (Henschke et al, 1999, 2000). Small pulmonary nodules, observed on the initial scan, are investigated further by high-resolution CT and classified as to their appearance. Nodules with evidence of calcification are presumed to be granulomas and are followed clinically. Nodules with homogeneous, opaque appearance ("ground-glass opacities") and irregular margins are investigated further.

Most of the nodules discovered by spiral CT are smaller than 1 cm, and most are benign, so that identifying the few that are very small carcinomas can be a challenge. With contemporary technology, **detailed three-dimensional images of the nodules are available for precise measurements and study of their configuration, which can then be followed to detect possible progression on repeat scans** (Yankelevitz et al, 2000). It is assumed that nodules of irregular configuration or those that change shape or grow in size are more likely to be

malignant than smoothly configured nodules of constant shape and volume.

The institutions participating in these studies use different approaches to investigate the nature of suspicious nodules: some use large-caliber (18-gauge) needles to perform a “mini-biopsy” of the nodule; others **rely on cytologic evaluation of the nodules by percutaneous thin-needle aspirations** (Henschke et al, 1999, Yankelevitz et al, 2000). Most of the malignant lesions discovered by this approach are peripheral adenocarcinomas, a smaller number are squamous carcinomas (see Fig. 20-20). Unfortunately, the percutaneous aspirations are not without complications, as discussed in detail in Chapter 19. **Approximately 30% of the patients develop pneumothorax, although almost all are minor and resolve spontaneously without intervention.** Of concern has been the possibility of **tumor cell implantation** in the needle track. Sinner and Zajicek (1976) reported only one such instance in more than 1,250 lung cancer cases, and single, additional cases were reported by Moloo et al (1985) and Sacchini et al (1989). **This very rare complication is even more unlikely if fine-bore needles are used (< 0.6 mm diameter, 21-gauge).**

Results

Several groups of investigators have reported preliminary results of their studies, which include an early report from the US (Henschke et al, 1999), and a larger experience from Japan (Kaneko et al, 1996; Sone et al, 1998). It is clear that selection of the population at risk will impact results. Thus, the Henschke study admits men age 60 and higher with 10 or more years of smoking history. The **prevalence** of lung cancer on the first screen of 1,000 patients was 2.7% (27 cases), whereas on the next 1,184 examinations, which includes

P.683

a second screening of the same group and gives an **approximation of incidence**, there were only 7 new cases (0.6%). More than 80% of the cancers discovered were in surgically resectable stage I (see Fig. 20-20).

In other studies dealing with lesser risk populations, the prevalence of lung cancer was much lower. In the study by Sone et al (1998), which accepted smokers and nonsmokers of both sexes, age 40 and higher, lung cancer was detected in 40 of 7,847 patients (0.5%), and was the same for smokers and nonsmokers. Miettinen (2000) discussed the cost-effectiveness of the screening programs. At the time of this writing (2004), none of the health agencies of the US government or the American Cancer Society have formally endorsed these screening programs. In describing a statistical model of expected true and false-positive findings with helical CT for lung cancer detection, Mahadevia et al (2003) considered estimates of the uncertainty of benefits, the potential harm of false-positive invasive tests and high costs, and concluded that these screening examinations were not cost-effective.

UNCOMMON PRIMARY MALIGNANT TUMORS OF LUNG

Neuroendocrine Tumors

The neuroendocrine tumors as a group have been separated from other pulmonary neoplasms by histology and their presumed common origin in the endocrine bronchial cells (Kulchitsky's cells). They are characterized by the presence of **membrane-bound, dense-core neuroendocrine cytoplasmic inclusions in electron micrographs**, and **positive immunocytochemical reactions with specific monoclonal antibodies for chromogranin, synaptophysin, or for polypeptide hormones such as serotonin, ACTH, gastrin, etc.** (see

also Chap. 45). **Endocrine activity may be evident clinically in the form of various polypeptiderelated syndromes, such as the carcinoid syndrome** (see below). The prototypical neuroendocrine tumor of lung is the carcinoid and its variants. Small-cell (oat cell) carcinoma and its relationship to endocrine tumors was discussed above.

Carcinoid Tumors

Histology and Clinical Data

Carcinoid tumors of the lung occur in adults of any age and are unrelated to cigarette smoking. The tumors are generally circumscribed and grow under and lift the sometimes-ulcerated overlying bronchial epithelium. They present most frequently as a nodular tumor projecting into and partially obstructing a major bronchus (Fig. 20-28A). Like their counterpart in the bowel, carcinoids of the lung are **composed of nests, rosettes, or ribbons of tightly packed, quite regular, small, polyhedral cells** (Fig. 20-28B). **Variants may be composed of spindle cells** (Fig. 20-28C) **or contain an admixture of large, eosinophilic oncocytic cells with granular cytoplasm**. They typically produce serotonin and sometimes other polypeptide hormones, and stain for chromogranin, a neurosecretory marker (Fig. 20-28D). Carcinoid tumors commonly arise in the bowel and their products are detoxified in liver. The **carcinoid syndrome** (i.e., flushing of skin, diarrhea, bronchospasm, and sometimes endocardial and valvular fibrosis of the right side of the heart) results from **serotonin secretion** by metastatic carcinoid in the liver, bypassing detoxification (see Chap. 24). Interestingly, the carcinoid syndrome has been described, not only with pulmonary carcinoid, but also in bronchogenic carcinoma (Majcher et al, 1966).

The majority of carcinoids arise in and partially obstructs larger bronchi, and cause symptoms at an early, still-localized stage. They are diagnosed by conventional radiographic studies and bronchoscopic biopsy or brushing cytology. The uncommon peripheral carcinoids are diagnosed by needleaspiration cytology or a needle core biopsy. If detected early, they can be cured by surgery. If untreated, carcinoids will gradually enlarge and most eventually metastasize.

Cytology

As the tumors are covered entirely or almost entirely by intact bronchial epithelium, and since the tumor cells are quite coherent and do not exfoliate easily, an initial **diagnosis of pulmonary carcinoid by cytologic examination of sputum or bronchial secretions is highly unlikely**. However, the diagnosis has been made on postbronchoscopy sputum specimens from patients suspected of bronchogenic carcinoma, as a consequence of mucosal disruption during the diagnostic procedure. We have also observed tumor cells in **sputum specimens of patients with metastatic carcinoid of intestinal origin**, and in patients with the related pancreatic islet cell tumors (see below).

The diagnosis is usually established on **bronchial brush specimens or by percutaneous needle aspiration**. In **postbronchoscopy sputum or bronchial brush specimens**, the cells of bronchial carcinoid are 15 to 20 μm in diameter. They are typically dispersed (Fig. 20-29A,B) or in small groups, sometimes forming **flat, loosely structured gland-like clusters** (Fig. 20-29C) (Lozowski et al, 1979). Carcinoid tumor cells are generally uniform and have a characteristic appearance: variably cuboidal or rectangular with faintly basophilic transparent cytoplasm in Papanicolaou stain, and eccentric nuclei. The position of the nucleus gives a vaguely plasmacytoid appearance (Fig. 20-29B). The nuclear chromatin is finely granular, often

described as “salt and pepper.” There may be tiny nucleoli.

In the **uncommon variant of carcinoid with oncocyctic cells** (Matsumoto, 1993), the smears may show the classical features of carcinoid with an admixture of **variable numbers of oncocytes, singly and in clusters** (Fig. 20-29D). The oncocytes are readily recognized as **larger cells about the size of macrophages, with abundant, granular, eosinophilic cytoplasm and small vesicular nuclei**. There have been reports in which the cytologic pattern is dominated by the presence of oncocytes (Ogino, 2000). Because primary oncocytomas of lung are exceedingly rare, **the finding of oncocytes in bronchial brush specimens or aspirates from a lung tumor should immediately raise the possibility of a carcinoid or, more remotely, a granular cell tumor**.

P.684

Figure 20-28 Carcinoid of lung. *A.* Gross appearance of a carcinoid tumor of lobar bronchus in an adult female. The smooth-surfaced polypoid tumor obstructs the lumen of the bronchus. *B.* Histologic section showing cuboidal tumor cells in trabecular pattern or nests. *C.* Carcinoid tumor with an organoid spindle cell pattern. *D.* Immunoperoxidase reaction for chromogranin is strongly positive for neurosecretory granules in this needle core biopsy.

With increasing use of **percutaneous needle aspiration biopsy**, cytologic samples of bronchial carcinoids are now being seen more frequently (Nguyen, 1995). The cytologic presentation in needle aspirates is similar to bronchial brushing specimens but usually more cellular (Collins and Cramer, 1996). **Occasional large, sometimes multinucleated giant cells may be observed, not an uncommon finding in endocrine tumors of all origins**. In an occasional case, the nuclei may be more darkly stained, but we have not observed the markedly hyperchromatic nuclei described by Kyriakos and Rockoff (1972) in brush specimens.

Peripheral carcinoids are often composed of spindle cells (see Fig. 20-28C) and may yield fusiform or polygonal cells (Jordan et al, 1987) with spindle-shaped nuclei and scant cytoplasm in percutaneous needle aspirates. Generally, the **cytologic diagnosis of**

carcinoid is suggested by monotony of nuclear size, delicate “salt and pepper” chromatin structure, and absence of necrosis. As noted, carcinoids may have a rosette pattern in histologic section, and Pilotti et al (1983) described two carcinoids with **glandular features in needle aspirates**. In such very unusual cases, the differentiation of carcinoid from adenocarcinoma and sometimes from SSC may cause diagnostic problems. Strong staining for chromogranin (see Fig. 20-28D) supports the diagnosis of carcinoid.

Atypical Carcinoid Tumors

Synonyms: well-differentiated neuroendocrine carcinomas, peripheral SSCs resembling carcinoid tumors.

Histology

The uncommon atypical carcinoid tumors were defined by Arrigoni et al (1972) as circumscribed **tumors with the basic histologic pattern of carcinoid but characterized by tumor cell pleomorphism; variably sized and atypical nuclei, a high mitotic rate; prominent nucleoli and focal necrosis**. They have a more aggressive clinical course than conventional carcinoids, and in 1983, Gould et al introduced the term **well-differentiated neuroendocrine carcinoma** to describe these tumors. Because even the conventional carcinoid may be malignant, however, there seems little rationale for this designation. Mark and Ramirez (1985) preferred to call them peripheral SSCs resembling carcinoid tumors. Craig and Finley (1982) described a spindle cell variant of these tumors, which is more likely to arise in peripheral lung, and more likely to be seen in percutaneous needle aspirates. The current WHO nomenclature is simply “atypical carcinoid.”

All of these designations pertain to the same group of uncommon lung tumors that combine the basic histologic features of carcinoid tumors with focal areas of anaplastic

P.685

cell growth, mimicking SSC of intermediate type. By high-resolution image analysis, the nuclei of anaplastic carcinoids are intermediate between conventional carcinoid and SSC (Larsimont et al, 1990). **Whereas atypical carcinoids have a more aggressive clinical course than the conventional carcinoids, they offer a significantly greater chance of surgical cure than SSC** (Ferguson et al, 2000).

Figure 20-29 Cytologic patterns of carcinoid tumor of lung in FNA and bronchial brushings. *A.* Pulmonary carcinoid tumor in a 34-year-old woman. In the aspiration smear, the cells are evenly spread with uniform, ovoid or round nuclei, delicate chromatin and tiny nucleoli. There are few clusters of overlapping cells and no molding or necrosis. *B.* Aspirate of carcinoid tumor in which there are flat plaques or clusters of cells with deeper-staining cytoplasm and peripheral nuclei of plasmacytoid appearance. *C.* Bronchial brush specimen with flat clusters and single tumor cells with a moderate amount of palestaining cytoplasm, uniform, round or slightly ovoid nuclei with delicate “salt and pepper” chromatin and small nucleoli. *D.* Oncocytic cell type of carcinoid in aspiration smear. The tumor cells have abundant eosinophilic cytoplasm.

Cytology

Experience with the cytology of these tumors is limited. Frierson et al (1987) describe eight such tumors in samples obtained by percutaneous needle aspiration. The cells differed from those of typical carcinoid by more likely formation of cell clusters, more **variability in nuclear size**, and the presence of some cells with **increased nuclear hyperchromasia or prominent nucleoli**. **Atypical carcinoid was distinguished from SSC, intermediate type, by tumor cells often arranged in organoid pattern with more abundant cytoplasm, open, nonpyknotic nuclei, a lower level of nuclear abnormalities, and absence of nuclear molding or necrosis (Fig. 20-30).**

In one cytologic study of 22 cases, Jordan et al (1987) described small sheets and cohesive **clusters of polygonal or fusiform cells with clear cytoplasm, medium-sized ovoid nuclei with single or multiple nucleoli, and rosette-like acinar clusters with palisading. Molding of nuclei was absent.** There were 13 long-term survivors among the 22 patients.

Although these features may be evident on retrospective review of histologically documented cases, in practice, the **prospective cytologic diagnosis of this group of tumors is extremely difficult**. In several cases from the Massachusetts General Hospital, seen courtesy of Dr. Wanda Szyfelbein, and personally reviewed (LGK), the diagnosis rendered was **carcinoid with atypical features**. In practice, regardless of cytologic classification, **resectable lung neoplasms should be excised and examined histologically so long as the diagnosis is not that of an oat cell carcinoma or SSC, intermediate type.**

Large-Cell Neuroendocrine Carcinomas

Some non-small-cell undifferentiated carcinomas of lung are distinguished from other non-small-cell tumors

P.686

only by expression of neuroendocrine markers in immunocytochemical stains for chromogranin, synaptophysin, etc. They constitute an estimated 3% of lung cancers (Jiang et al, 1998), and **cannot be differentiated from the morphologically similar tumors by conventional cytology alone.**

Figure 20-30 Atypical carcinoid of lung. *A.* FNA of an atypical peripheral carcinoid of lung in a 73-year-old woman. There are occasional cells with large nuclei among an otherwise generally uniform but unevenly distributed population of cells. The aspirate could be mistaken for adenocarcinoma. *B.* A thick part of the same smear in which the trabecular and nesting patterns of carcinoid tumor are evident side by side. *C.* Histologic section. Chromogranin stain was strongly positive. (*A,B*: Diff-Quik stain.)

Minute Pulmonary Chemodectomas (Tumorlets)

The chemodectomas, first described by Whitwell (1955), are minute neuroendocrine tumors, often multiple, derived from Kulchitsky cells and believed to be related if not identical with carcinoids. Arioglu et al (1998) reported a case of **Cushing's syndrome** caused by corticotropin-secreting pulmonary tumorlets. We know of no case diagnosed by cytology, however, one should be aware that high-resolution spiral CT examinations may lead to the discovery and needle biopsy of a tumorlet.

Adenoid Cystic Carcinoma

Histology

These are highly malignant tumors of slow evolution, corresponding to the adenoid cystic carcinoma of salivary gland origin (Conlan, 1978). They are derived from **bronchial mucous glands**, and are therefore tumors of trachea and large bronchi. They have a very characteristic appearance, composed of **sheets of small, quite uniform cells, forming cystic spaces filled with homogeneous hyaline material that is derived from reduplicated basement membrane material** (Fig. 20-31A). While they are common in the salivary glands, adenoid cystic carcinomas are uncommon in the lower respiratory tract. For comments on such tumors in the trachea, see Chapter 21, and in the salivary glands, see Chapter 32.

Cytology

Adenoid cystic carcinomas do not easily exfoliate, and the diagnostic cells are more likely to be found in bronchial brushing specimens than in sputum, and more often in recurrent than in

primary tumors. The cytologic presentation is quite characteristic: **clusters of uniform, small cells with scanty cytoplasm and monotonous, dark nuclei, arranged around a core of homogeneous basement membrane material, which is faintly stained either cyanophilic or eosinophilic with the Papanicolaou stain** (Fig. 20-31B). The material stains purple with Diff-Quik and other metachromatic stains. In **percutaneous aspirates**, we have observed tumor cells forming large **overlapping spherical structures** composed of uniform small cells. Hyaline cores were not visible within the tumor globes, but could be seen as isolated extruded bodies in the smear background. In the absence of the hyaline cores, one may make a descriptive diagnosis of a tumor composed of small cells, and suggest adenoid cystic carcinoma as one possibility, but a more specific diagnosis may not be possible. The cytology of metastases from salivary gland tumors is identical.

P.687

See also Chapter 32.

Mixed Malignant Tumors (Carcinosarcomas)

There are very uncommon malignant tumors in which a **malignant epithelial component is associated with a sarcomatous component such as rhabdomyosarcoma** (Davis et al, 1984; Takeda et al, 1994; Berho et al, 1995; M. Koss et al, 1999). Ishizuka et al (1988) and Parafiniuk et al (1994) reported the cytologic findings in sputum of patients with such a tumor. **Cells of ordinary squamous carcinoma were associated with tumor cells of variable configuration with cytoplasmic cross-striations, classified as rhabdomyoblasts.** Finley et al (1988) reported the immunocytochemistry and electron microscopy studies of a needle aspirate of pulmonary carcinosarcoma. The histology and cytology of these tumors in the uterus are described in Chapter 17.

Pulmonary and Pleuropulmonary Blastomas

Pulmonary blastomas are exceedingly uncommon and highly malignant tumors of **embryonal type** that may be compared to Wilms' tumor of the kidney (see Chap. 40). The tissues comprising the tumor resemble fetal lung. They are composed of **malignant embryonal connective tissue within which are tubular structures lined by cuboidal or columnar cells mimicking primitive bronchioles** (Barnard, 1952; Spencer, 1961; Souza et

al, 1965). Variants may be entirely epithelial or mesenchymal. Although pulmonary blastomas are often considered tumors of children and young adults, they may occur at any age, and the median age is reported to be in the fourth decade (M. Koss et al, 1991).

Non et al (1976) described the cytologic presentation of one such case in the **sputum** of a 73-year-old patient. He observed numerous clusters of **large cancer cells derived from adenocarcinoma** together with **clusters of smaller cells derived from the undifferentiated sarcomatous component**. Spahr et al (1979) also reported a single case of blastoma in which cells of carcinoma were accompanied by small stromal cells. Jacobsen and Francis (1979) described 10 cases of pulmonary blastoma in elderly patients of both sexes, studied by several cytologic techniques. **Most specimens were diagnosed as carcinomas of various types by sputum and bronchial washings**. The diagnoses of **sarcoma and of a "mixed tumor"** were each rendered only once in **percutaneous aspiration biopsy material**. It is evident from their report that cytologic sampling by routine techniques may be biased in favor of carcinoma; the sarcomatous component of a mixed tumor is best recognized by direct FNA sampling.

Pleuropulmonary blastoma, an embryonal malignant tumor of children, arises in lung in association with pleura. Unlike the pulmonary blastoma of adults, it is composed of **embryonal mesenchymal elements without a malignant epithelial component** (Manivel et al, 1988). Nicol and Geisinger (2000) described a case in which a percutaneous needle aspirate yielded a **mixture of primitive blastemal cells and spindle-shaped cells**, presenting as dispersed single cells and cohesive aggregates. In reports by Gelven et al (1997) and Drut and Pollono (1998), **myxoid matrix was present as well**. The differential diagnosis includes all the small, round cell malignant tumors of childhood.

Sarcomas

For an in-depth discussion of soft part sarcomas, see Chapter 35. Primary pulmonary sarcomas are very uncommon and few are intrabronchial in origin. Those that arise in the lung seldom erode the bronchial wall (except for malignant lymphomas) (see below), and they do not exfoliate easily. Thus, finding tumor cells of sarcoma in sputum is an exceptional event. On the other hand, aggressive investigation of lung masses by **percutaneous or transbronchial needle aspiration biopsy** may lead to at least a presumptive diagnosis of sarcoma. The most common are leiomyosarcoma, malignant fibrous histiocytoma and fibrosarcoma, but precise classification of tumor type by cytology is difficult (Guccion and Rosen, 1972; Nascimento et al, 1982; Suster, 1995; Keel et al, 1999).

Leiomyosarcoma

These uncommon tumors, composed of bundles of malignant smooth muscle cells, may form an intrabronchial

P.688

polypoid mass, as in a case described by Krummerman (1977) (Fig. 20-32A), but more often appear as parenchymal tumors. There are a few cases on record in which the **spindly malignant cells** were observed in **sputum** (Fleming and Jove, 1975), **bronchial brushings** (Sawada et al, 1977), or in a **bronchial aspirate** (Krummerman, 1977). In most cases, the diagnosis is obtained by **percutaneous FNA**.

In the reported cases, **spindly, but fairly plump** malignant cells were observed (Fig. 20-32B), some with bifurcated ends. We observed one such case in a 17-year-old male with a very large

intrapulmonary tumor mass who shed some of the relatively inconspicuous spindly tumor cells in sputum. The diagnosis was confirmed by a percutaneous needle aspirate that disclosed densely clustered and dispersed elongated tumor cells with moderately enlarged, finely granular nuclei and conspicuous, irregular, but not very large nucleoli (Fig. 20-32C). The tumor was resected, and the diagnosis of leiomyosarcoma was confirmed in histologic material.

Malignant Fibrous Histiocytoma

These tumors, cytologically similar to fibrosarcoma and leiomyosarcoma, have been reported by Barbas et al (1997) to yield **spindle-shaped cancer cells with “comet” configuration** in a bronchial brush specimen. Sampling is scanty at best in bronchial specimens, and much better in percutaneous needle aspirates. Hsiu et al (1987) and Kawahara et al (1988) diagnosed malignant fibrous histiocytoma by needle aspirate. The smears showed a mixture of malignant spindle and polygonal cells with a few giant cells. In addition to the cytologic patterns described above, we have seen aspirates of a small number of these tumors that also contained cells with ample cytoplasm mimicking an epithelial tumor.

Figure 20-32 Leiomyosarcoma of lung. *A,B.* Case of Dr. Krummerman showing a polypoid spindly leiomyosarcoma that projected into the bronchus (*A*), and yielded spindly, smooth muscle tumor cells in a bronchial aspirate (*B*). *C.* Aspiration biopsy of lung in another patient, a 17-year-old boy. Note elongated cancer cells.

The diagnosis of **Kaposi's sarcoma** must be considered in AIDS patients and others who are immunosuppressed and present with space-occupying lesions of the lung. One of us (LGK) has seen the percutaneous FNA cytology slide from a case of Kaposi's sarcoma reported by Haramati (1995). In this and a few other cases, the smears contained thick bundles and dispersed spindly cells with enlarged oval, hyperchromatic nuclei in a background of blood. In the proper clinical setting, it is possible to make a diagnosis of spindle cell tumor consistent with Kaposi's sarcoma (Fig. 20-33) and in doubtful cases demonstrating expression of herpes virus 8 in tumor cells.

Synovial sarcoma, a malignant soft-tissue tumor commonly found in the extremities in

association with synovial or bursal tissues, may rarely arise in other sites including lung and/or pleura (Essary et al, 2002). The tumor may be biphasic with spindle sarcomatous and epithelial components or a monophasic spindle-cell sarcoma. We have encountered one such case, presenting as a solitary intraparenchymal monophasic spindle-cell sarcoma, but have no experience with FNA cytology. Costa (1997) reported the FNA cytology of a metastatic, monophasic synovial sarcoma in the lung. The tumor was characterized by the presence of groups of spindle cells with ovoid nuclei and scant cytoplasm

P.689

(for further discussion of these tumors, see Chap. 35).

Figure 20-33 Kaposi's sarcoma involving lung in a patient with AIDS. An FNA of lung tumor showing spindly tumor cells singly and in small clusters. The cytologic findings were consistent with diagnosis of Kaposi's, which was subsequently confirmed.

Other Sarcomas

Medalie et al (1998) reported a patient with **pulmonary artery sarcoma diagnosed by FNA**. The diagnosis was made by a finding of pleomorphic and spindly malignant cells in an FNA of a lung nodule from a patient with an intraluminal filling defect of the left main pulmonary artery.

Differential Diagnosis of Spindle-Cell Sarcomas

The **differential diagnosis of primary pulmonary spindle-cell sarcomas** should include the **solitary fibrous tumor of pleura (fibrous mesothelioma: pleural fibroma)**. It is a **benign, often pedunculated, spindle-cell fibroblastic pleural tumor** that is typically rich in collagen, does not exfoliate, and is often sparsely cellular in percutaneous needle aspirates. The **spindle cells obtained by needle aspirate show varying degrees of nuclear atypia, and are immunoreactive with CD-34**. The smears frequently contain **thick collagen and sometimes-recognizable capillaries** as well as **clusters of mesothelial cells** (Ali et al, 1997; Apple et al, 1997; Drachenberg et al, 1998). Sarcomatous malignant mesothelioma must also be included in the differential diagnosis. Primary tumors of the pleura are discussed in Chapter 26.

Lymphangiomyomatosis is an uncommon, cytologically "benign," but locally aggressive vascular tumor that is rich in smooth muscle and can mimic low-grade spindle-cell sarcoma in a FNA. Buhl et al (1988) drew attention to the **organoid configuration of tumor cells as a possibly useful diagnostic feature in the needle aspirate**. These tumors are not likely to

exfoliate into sputum or bronchial specimens. Ackley et al (1998) reported a case with lymph node metastases diagnosed by needle aspiration cytology.

In general, the cytologic presentation of all sarcomas of lung is similar, and classification of tumor type on cytologic material alone is virtually impossible. A specific classification requires histologic material and often a battery of immunostains.

Further, it should be emphasized that **malignant spindle cells in sputum or a bronchial aspirate are much more likely to be derived from a spindle cell or sarcomatoid carcinoma than a sarcoma.** Thus, it is quite possible for a sarcoma of lung to be misinterpreted as spindle-cell carcinoma. Conversely, a **mistaken diagnosis of sarcoma** may be due to exfoliated cells of a primary or metastatic spindle-cell carcinoma in lung (Nakajima, 1999).

A very unusual example of **exfoliated, degenerating smooth muscle cells** resembling the cells of a spindle-cell sarcoma was reported by Takeda and Burechailo (1969) in a patient with **Wegener's granulomatosis and ulcerative tracheobronchitis.** Thus, **knowledge of clinical data is indispensable** before cytologic diagnosis of rare entities can be rendered. With the present increasing use of percutaneous needle aspiration biopsy, additional examples of these exceedingly rare primary pulmonary sarcomas certainly will be reported.

Primary Pulmonary Lymphomas

Lymphomas originating primarily within the lower respiratory tract are rare. It must be assumed that they **arise within intrapulmonary lymph nodes or in deposits of lymphoid tissue.** The current classification of malignant lymphomas is complex, based on cytology, antigen expression by immunocytochemistry and flow cytometry, and cytogenetics. An overview is provided in Chapter 31. In this description of the cytologic presentation of malignant lymphomas in the lung, it is sufficient to group them into categories of **small-cell and large-cell lymphomas and Hodgkin's disease.** The cytologic presentation of lymphomas secondarily involving lung is identical (see below).

In an authoritative review of primary pulmonary lymphomas, 36 cases were reported from a major cancer center by L'Hoste et al (1984). Twenty-one patients had a small-cell plasmacytoid lymphoma; most of the others had a large-cell lymphoma. Many of the small-cell lymphomas were originally diagnosed as pseudolymphoma, based on their slow clinical evolution. Most have been reclassified as mucosa-associated lymphomas (MALT lymphomas), and the term *pseudolymphoma* must now be considered obsolete.

P.690

In our experience, **primary small-cell lymphoma of lung cannot be diagnosed with confidence from exfoliative cytology in sputum, bronchial washings, or brushings.** An abundance of uniform, morphologically normal lymphocytes or plasmacytoid cells, with or without intermixed lymphoblasts, may very well represent an inflammatory lesion or reactive hyperplasia of lymphoid tissue (see Chap. 19). Even in patients with known lymphocytic lymphoma and a pulmonary tumor, the presence of a uniform population of small lymphocytes, while consistent with lymphoma, cannot be considered diagnostic. In principle, it is possible to make the diagnosis if a monoclonal population of lymphoid cells is demonstrated, either by flow cytometry or by immunocytochemical staining of the cells on a slide, or if the diagnosis is confirmed by chromosomal karyotyping on a portion of the specimen (see Chap. 4). This is rarely possible in specimens of sputum, bronchial aspirates, or wash specimens.

Similarly, percutaneous needle aspiration biopsy of lung has been of little help in the diagnosis of primary pulmonary lymphocytic lymphoma, although the cytology of these tumors is better demonstrated in needle aspirates than in sputum or bronchial brushings. Needle aspirates do have the potential advantage of providing more material for immunocytochemistry and flow cytometry to confirm and classify suspected lymphoma.

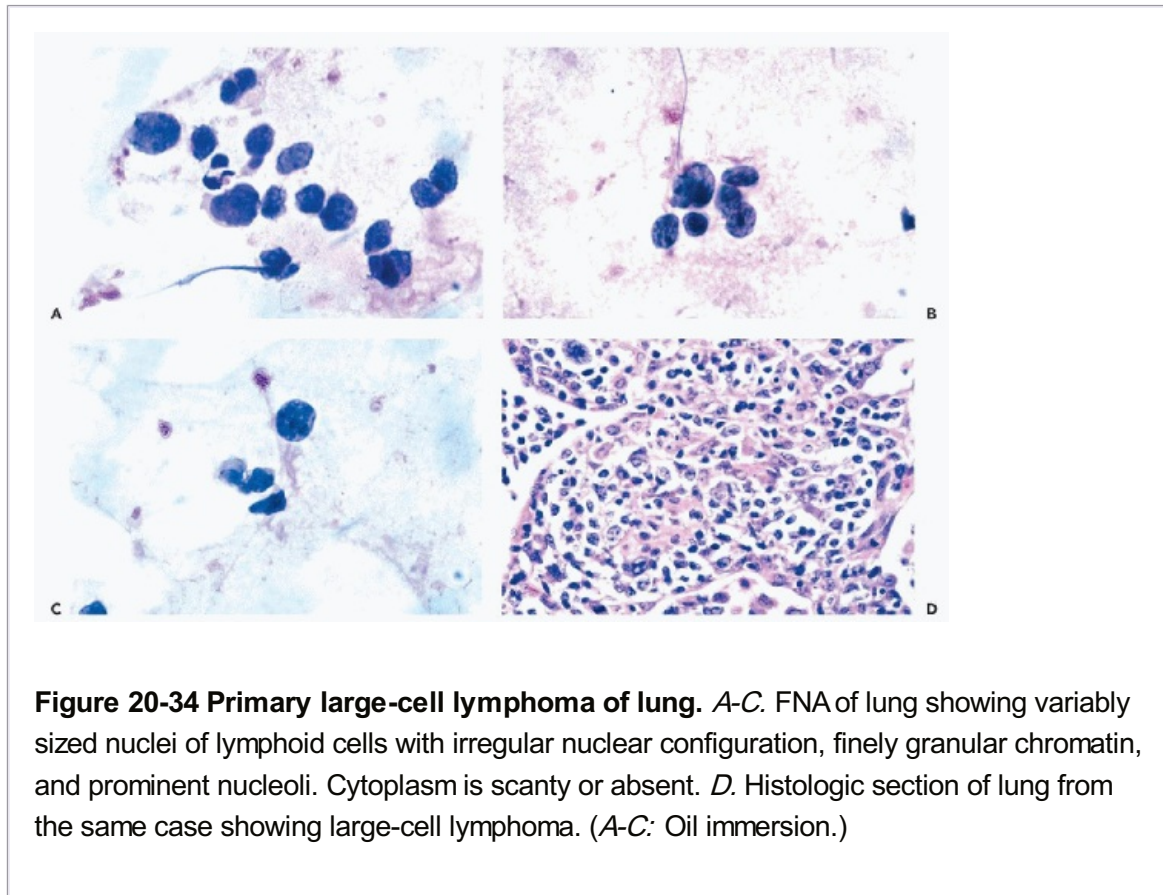

Figure 20-34 Primary large-cell lymphoma of lung. A-C. FNA of lung showing variably sized nuclei of lymphoid cells with irregular nuclear configuration, finely granular chromatin, and prominent nucleoli. Cytoplasm is scanty or absent. D. Histologic section of lung from the same case showing large-cell lymphoma. (A-C: Oil immersion.)

On the other hand, **large-cell lymphomas can be recognized in conventional cytologic specimens**, and particularly in FNAs. Bardales et al (1996) reported several such cases diagnosed by sputum cytology.

Cytology of Large-Cell Malignant Lymphoma

The exfoliated cells of large-cell lymphoma are comparable in size to SSC of the lung, and to metastatic small-cell malignant tumors from which they must be distinguished. The lymphoma cells have **round or oval, sometimes folded or indented nuclei with finely textured or vesicular chromatin and often-prominent nucleoli** (Fig. 20-34)). **Like SSC of lung, they may have a narrow rim of cytoplasm. However, the bizarre cell forms, variations in cell size and necrosis that are common in SSC are not seen in lymphoma. Most importantly, the lymphoma cells lie singly, only touching each other in crowded cell specimens, unlike the loosely coherent clusters of superimposed cells of SSC; cell molding, which is so common in SSC, is not seen in lymphoma. The degree of nuclear pyknosis and hyperchromasia is much greater in SSC than in lymphoma, whereas nucleolar prominence is significantly greater in large-cell lymphoma.**

A case of the very rare “signet ring cell” lymphoma of the lung was described by Vernon (1981). The tumor mimics

small-cell adenocarcinoma. For further discussion of this and other common and uncommon types of malignant lymphoma, see Chapter 31.

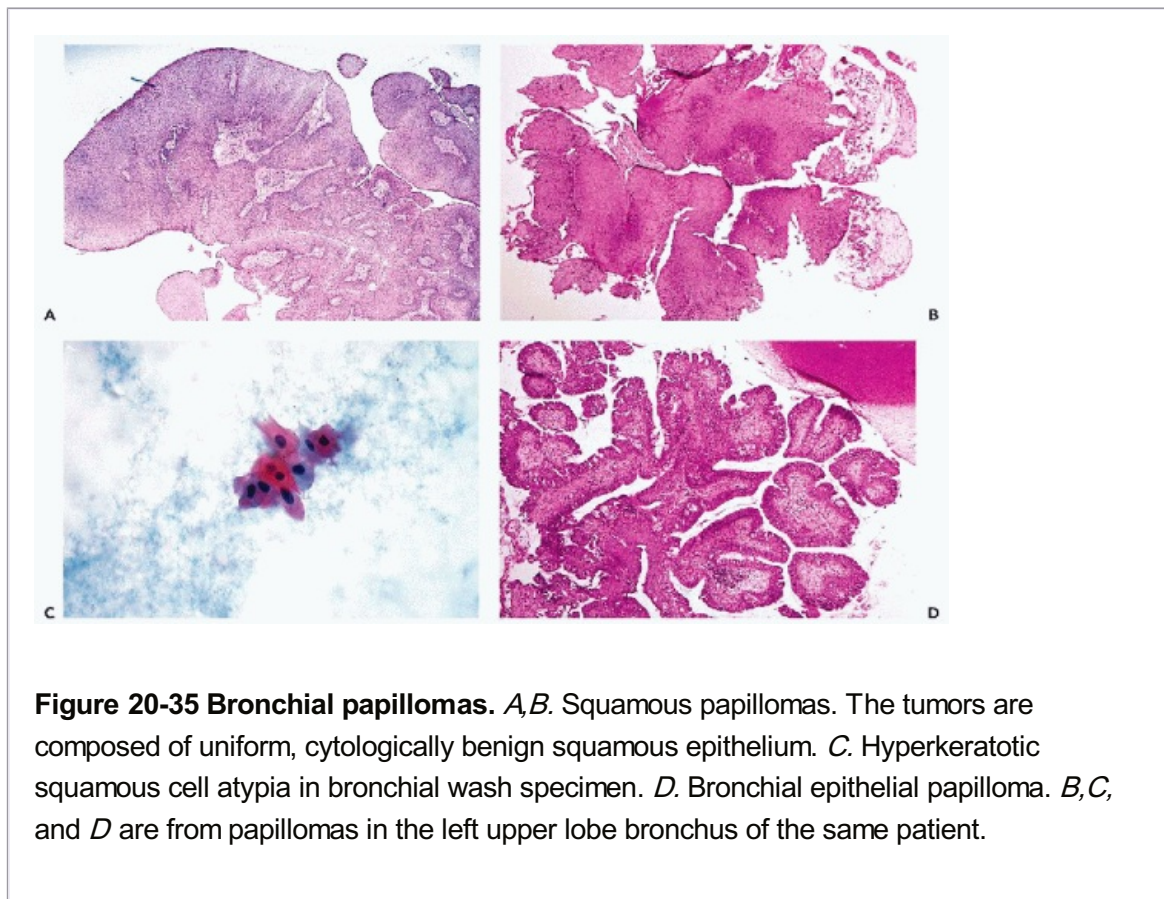

When lymphoma is suspected and the cytologic diagnosis is uncertain, one can gain considerable help from the ancillary diagnostic techniques of cytogenetics, immunocytochemistry and flow cytometry (see Chaps. 4, 45, and 47).

Primary Hodgkin's disease of the lung is exceedingly rare (Kern et al, 1961). To date, we have not encountered a single case diagnosed initially by cytology. The lung is commonly involved secondarily, however, particularly in cases of **mediastinal Hodgkin's disease**, and there are several examples of such cases diagnosed by cytology, as discussed below.

Langerhans' cell tumors and their variants are discussed in Chapter 19.

PRIMARY BENIGN TUMORS AND TUMORS OF LOW MALIGNANT POTENTIAL

As a group, the primary benign tumors of lung do not exfoliate well and, when present, the exfoliated cells may not be recognized as tumor cells. Cytology plays a role here when specimens are obtained by bronchial brushing or by needle aspirates.

Squamous Papillomas of Bronchi

These uncommon lesions are usually observed in children and young adolescents as multiple papillary squamous tumors involving the larynx, trachea, and bronchi (**juvenile papillomatosis**), and are discussed in Chapter 21. HPV has been detected in mucosal swabs of these lesions (Sun et al, 2000). Their growth may subside after puberty, and without other predisposing factors, they progress to carcinoma only on rare occasions (Guillou et al, 1991).

In contrast, the very rare histologically similar **squamous papillomas of bronchus** of older

adults (Fig. 20-35) have a high risk of progression to squamous carcinoma (DiMarco et al, 1978). The tumors resemble condylomata acuminata of the genital tract (see Chap. 11), and HPV has been demonstrated in koilocytes of this lesion by means of anti-HPV antibody and electron microscopy (Trillo and Guha, 1988); the subtype of virus was not determined. Rubel and Reynolds (1979) described **marked dyskaryosis and koilocytosis of squamous cells in bronchial brushings, similar to the HPV-induced changes in the uterine cervix.** **Hyperkeratotic atypia of squamous cells** (Fig. 20-35C) was

P.692

noted in a bronchial wash specimen from the patient illustrated in Figure 20-35B who also had a **bronchial papilloma** surfaced by benign bronchial epithelium (Fig. 20-35D). The only other case of which we are aware in which a solitary bronchial papilloma presented with cellular abnormalities in a cytologic specimen was described by Roglic et al (1975). Although the investigators failed to diagnose the lesion prospectively, a review of the photographic illustrations in their report strongly suggests that **atypical squamous cells resembling koilocytes were present in the bronchial brushings. Nonspecific atypias of squamous cells were observed in sputum** of two patients seen in consultation by one of us (LGK). In another very recent case that we saw, there was sufficient cytologic atypia in the intraoperative imprint cytology of a squamous papilloma from the upper respiratory tract to raise suspicion of squamous carcinoma.

The **differential diagnosis of benign squamous papilloma includes well-differentiated exophytic squamous carcinoma.** The two entities may have identical gross and superficially similar microscopic appearances, but even very orderly squamous carcinomas have significant atypia of squamous cells and usually demonstrable invasion of the underlying tracheobronchial wall. Such tumors shed squamous cancer cells, some of which may resemble koilocytes. The possibility of HPV infection has been raised in these cases (Syrjänen et al, 1989). There are reports of HPV type 16 identified in a verrucous carcinoma of the larynx (Brandsma et al, 1986), and HPV type 11 in specimens from a patient with malignant laryngotracheobronchial papillomatosis of the lung metastatic to the liver (Byrne et al, 1987).

Figure 20-36 Granular cell tumor of bronchus. A,B. Histologic section of a granular cell tumor of bronchus. The tumor lies under the epithelium and is composed of large cells with

abundant, granular, eosinophilic cytoplasm. Nuclei are relatively small and round. *C,D*. Bronchial brush specimen shows coherent groups of large cells with abundant, delicate, finely granular cytoplasm and vesicular nuclei with smooth nuclear border and small nucleoli. Cell boundaries are indistinct at high magnification.

Granular Cell Tumor

Benign granular cell tumors have been observed in many different organs including the tongue, skin and breast, as well as the larynx and bronchus (Majmudar et al, 1981) and uncommonly in peripheral lung (Schulster et al, 1975). While extremely unusual, there are examples of malignant granular cell tumors in the bronchus (Steffelaar et al, 1982; Klima and Peters, 1987; Parayno and August, 1996). The tumors are of uncertain origin, although probably derived from the neural Schwann cell (Alvarez-Fernandez and Carretero-Albinana, 1987). In the bronchus, they are **subepithelial in location and composed of sheets of large cells with small nuclei and abundant, granular eosinophilic cytoplasm** that contains numerous lysosomes (Fig. 20-36A,B). Granular cell tumors may grow to substantial

P.693

size and cause bronchial obstruction, thereby clinically mimicking bronchogenic cancer. Naib and Goldstein (1962) were the first to describe the cytologic presentation of this tumor, followed later by Glant et al (1979).

Cytology

Granular cell tumors do not exfoliate easily, and we are unaware of any cases diagnosed by sputum cytology. In **bronchial brushings and aspirates, the tumor presents in cohesive sheets of large cells with slightly hyperchromatic but round or oval nuclei, visible nucleoli and abundant, granular, faintly basophilic cytoplasm. Cell borders are ill-defined** (Fig. 20-36C,D). **Single tumor cells are usually poorly preserved, and their cytoplasm is often frayed** (Thomas et al, 1984; Fuzesi et al, 1989; Chen, 1991; Guillou et al, 1991). Smith et al (1998) described a granular cell tumor in the **posterior superior mediastinum**, diagnosed by percutaneous needle aspiration. As in bronchial brush specimens, the tumor cells were large, polygonal or spindly, with granular cytoplasm and indistinct cell borders. In agreement with Glant et al (1979), we found that **the most important feature distinguishing cells of granular cell tumor from macrophages is the coherent clustering of the tumor cells, virtually never seen with macrophages**. The distinction between benign and malignant granular cell tumors is based on conventional cytologic criteria, and on clinical presentation; however, the malignant granular cell tumors are so rare that the reader is cautioned not to make the diagnosis without very strong evidence.

Oncocytoma

These benign tumors are fairly common in the salivary glands and in the thyroid, less common in other organs such as the kidney, but are **extremely rare in the lung where they may be related to carcinoid tumors** (see above). Pulmonary oncocytomas, like those at other sites, are composed of **sheets of large, eosinophilic cells with large, sometimes multiple, often hyperchromatic nuclei. Characteristically, the cytoplasm of the tumor cells is filled with mitochondria** (Black, 1969; Fernandez and Nyssen, 1982; Alvarez-Fernandez and Carretero-Albinana, 1987; Santoz-Briz et al, 1977).

The cytology of bronchogenic oncocytoma was described in a case report by Cwierzyk et al (1985). **They observed large cells with granular cytoplasm, dark nuclei, and prominent nucleoli in bronchial brushings, similar to the cells of oncocytomas of other organs.** Laforga and Aranda (1999) recently described a case of multicentric oncocytomas of the lung studied by FNA in which cell aggregates and fragments of tissue were made up of rounded tumor cells with granular cytoplasm that reacted immunocytochemically with anti-mitochondrial antibodies.

Clear Cell (Sugar) Tumor

These are very rare, sharply demarcated benign lung tumors of unknown histogenesis, so named by Liebow and Castleman (1971) because of a strongly positive periodic acid-Schiff (PAS) reaction for glycogen content in the clear cytoplasm of the tumor cells. The tumors do not shed cells into sputum or bronchial secretions. In a percutaneous aspirate, Nguyen (1989) described **large irregular clusters of polygonal and spindle-shaped, benign-appearing cells with finely vacuolated, granular, PAS-positive cytoplasm and small nuclei.** Large cells with granules radiating out from the nucleus were referred to as “spider” cells. The tumor cells may contain **finely granular brown lipochrome pigment** and, since the cells **react with HMB-45 antibody** to pre-melanosomes, the diagnosis of melanoma has to be excluded. The differential diagnosis must include other clear-cell tumors, including the rare clear-cell bronchogenic carcinoma and metastatic tumors with clear cytoplasm, such as renal cell carcinoma and clear-cell sarcoma.

Hamartomas

These are relatively common intrapulmonary **malformations** that may present as **coin lesions or may mimic lung cancer in roentgenologic images.** They are well-circumscribed tumors that shell out easily from lung parenchyma and have a chondroid or fibrous texture on a cut surface. Histologically, they are composed of **cartilage, fibrous or loosely structured fibromyxoid connective tissue associated with bronchial epithelium and rudimentary bronchial structures lined by epithelial cells of respiratory type** (Fig. 20-37A).

Hamartomas do not communicate with bronchi and cannot be diagnosed on sputum or bronchial material. Percutaneous needle aspiration is the only diagnostic method short of thoracotomy. Still, the aspirates are often unsatisfactory because the tumor is too firm for the needle to penetrate and is pushed away by it; the “screw needle” described in Chapter 19 was devised to overcome this. If an adequate sample is obtained, **fragments of loosely structured connective tissue, fibromyxoid stromal components** (which are S-100 positive), **and benign epithelium occasionally with bits of cartilage may be observed** (Fig. 20-37B-D) (Dahlgren, 1966; Ramzy, 1976; Sinner, 1982; Wiatrowska et al, 1995). The **epithelial cells, which are derived from the rudimentary bronchi, may show some atypia, including intranuclear cytoplasmic inclusions or nuclear holes** as described in Chapter 19.

Primary Pulmonary Meningioma

Meningiomas, whether primary or metastatic, are exceedingly rare in the lung, but have been described and may be multiple (see Lockett et al, 1997, for a review of reported cases). Ueno et al (1998) were able to make an intraoperative diagnosis on cytology imprints of a thorascopically resected tumor by the presence **of whorled nests of cells accompanied by psammoma bodies.** Minute meningotheliomatous tumors (Travis et al, 1999) or

chemodectomas are a different entity, and like tumorlets, they are not likely to be sampled. For further description of the cytology of meningiomas, see Chapter 42.

P.694

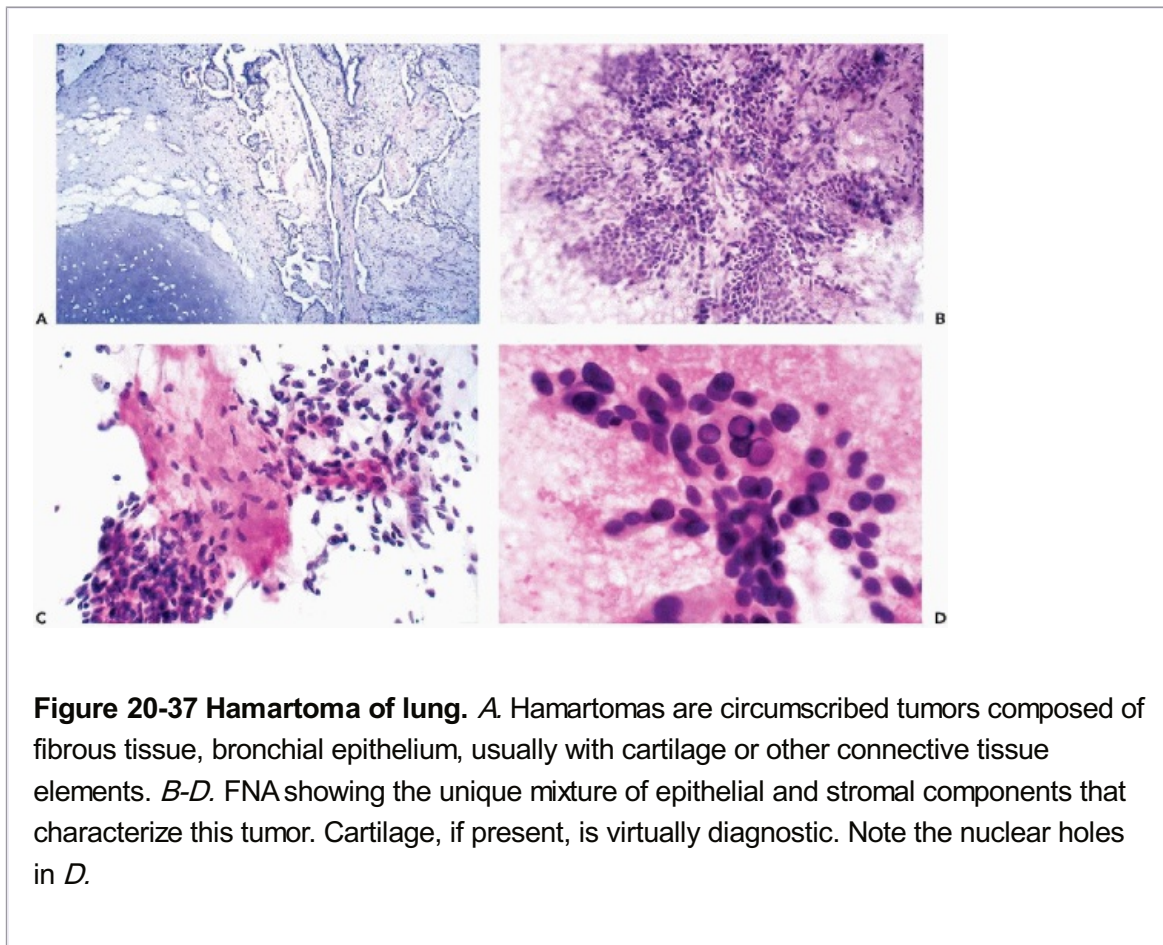

Figure 20-37 Hamartoma of lung. A. Hamartomas are circumscribed tumors composed of fibrous tissue, bronchial epithelium, usually with cartilage or other connective tissue elements. B-D. FNA showing the unique mixture of epithelial and stromal components that characterize this tumor. Cartilage, if present, is virtually diagnostic. Note the nuclear holes in D.

Inflammatory pseudotumor (plasma cell granuloma; inflammatory myofibroblastic tumor) was discussed in Chapter 19.

CYTOLOGY OF TUMORS METASTATIC TO THE LUNG (OTHER THAN LYMPHOMAS)

Patients with a past history of cancer at another site who develop a lung lesion must be thoroughly investigated with the following options to be considered:

- The lesion is a metastasis
- The lesion is benign with special consideration of:
 - a. Bacterial, viral, or mycotic infection
 - b. Effect of treatment by radio- or chemotherapy
- The lesion is a primary lung cancer

The benign lesions and complications of therapy have been discussed in Chapter 19. Here we consider **recognition of metastatic tumors by cytologic techniques**. The dominant thought in these investigations should be that the lesion is **not a metastasis until documented**. It is **important to emphasize that knowledge of the clinical findings and review of prior histologic and cytologic material are important safeguards** to ensure maximal accuracy of a diagnosis that often carries with it major therapeutic and prognostic consequences for the

patient.

Metastatic tumors in the lung may be identified by cytologic techniques (although not necessarily classified) in about half of the cases, including a great variety of tumors from many different primary sites (Koss et al, 1964). The probability of a positive diagnosis in any particular case is a function of tumor type, size and location in the lung, and the type of cytologic sample. Kern and Schweizer (1976) found **sputum cytology** to be as effective a diagnostic technique for metastatic cancer as for primary carcinoma of the lung. However, many metastatic tumors do not communicate with a bronchus, at least until they are relatively large. In our experience, the yield in sputum or bronchial aspirates is somewhat less for metastatic than for primary lung cancers (Koss et al, 1964). The yield from transbronchial or percutaneous needle aspirates is not affected by presence or absence of bronchial communication, but is more successful for larger metastases in easier reach of the aspirating needle.

Burke and Melamed (1968) reported on 92 consecutive patients (two-thirds males and one-third females) with (exfoliative) cytologic evidence of metastatic cancer to the lung, confirmed by histologic or clinical evidence. Their study antedated the common use of needle aspiration cytology. The

P.695

most frequent primary source of metastases was carcinoma of the esophagus, followed in order of frequency by colon, breast, lymphoma and leukemia, prostate, stomach, malignant melanoma, and a group of miscellaneous tumors of other sites. Eighty-six patients had radiographic evidence of metastatic disease, but **in 6 patients, sputum cytology revealed metastatic carcinoma in the absence of roentgenologic abnormalities**, possibly due to lymphangitic spread; in four of these six patients, an autopsy was performed and confirmed metastatic tumor. **In a more recent report from the same institution that included FNA cytology but excluded the esophagus, the most common primary sites of metastases to lung, in decreasing frequency, were breast, colon, kidney, bladder, and melanoma** (Zaman et al, 1986). It should be noted that these observations were from a cancer hospital with many referrals of problem cases and may not be representative of other institutions. However, it is clear that a broad spectrum of primary tumors metastatic to the lung is amenable to cytologic diagnosis.

Identification of Site of Origin of Metastatic Cancer

In the absence of clinical history, the cytologic diagnosis of primary versus metastatic cancer may be very difficult. With knowledge of age and gender, however, there are cytologic patterns in which preference for the primary site of origin of a metastatic carcinoma may be expressed.

Colon

Metastatic colonic carcinomas typically shed **columnar cells in clusters with one straight border, superficially resembling bronchial epithelial cells. The cells are not ciliated and they do not have a terminal bar. Nuclei are relatively large, larger than most bronchial cells, and ovoid, usually with coarsely textured chromatin** (Fig. 20-38A). **There is almost always tumor necrosis and the cytology smears have a dirty background with much necrotic and inflammatory cellular debris** (Fig. 20-38B). **An FNA may yield tall columnar cells aligned in a linear strip with a picket fence appearance, usually with some single cells, resembling bronchial cells** (Fig. 20-38C), but it should be remembered that few if any columnar bronchial cells are found in aspirates of peripheral lung, and columnar cells are rarely shed from primary adenocarcinomas of lung. Thus, the presence of **a linear strip of columnar cells in sputum, or in a bronchial or needle aspirate, whether obviously malignant or not, should arouse suspicion of metastatic colonic carcinoma, particularly if**

P.696

associated with necrotic cellular debris. Metastatic colonic carcinomas also shed mucin-secreting cancer cells (Fig. 20-38D), including so-called “signet ring cells.” The late Dr. John Frost emphasized that the nuclei of signet ring cancer cells “pushed the cell membrane out,” something one does not see with benign vacuolated cells. Necrosis is a frequent finding and colonic carcinoma must be considered if cells of adenocarcinoma with no specific features lie in a background of necrotic cellular debris.

Koizumi and Schon (1997) emphasized that **nuclear hyperchromasia may be absent in**

some metastatic colonic cancers, and that the cancer cells may have **pale nuclei with distinct nuclear membranes and prominent nucleoli** (Fig. 20-38D). These investigators also found that the metastatic tumors sometimes shed smaller cancer cells than the corresponding primary tumor, perhaps due to differences in needle aspirate versus brush cytology techniques.

Breast

Metastatic mammary carcinoma is by far the most common source of metastatic lung cancer in women. The tumors shed a great variety of **tumor cells that vary in size and configuration but generally match the histologic pattern of the tumor** (Fig. 20-39A,B). **Most often, they present in groups and clusters, sometimes in papillary configuration, but also as single malignant cells that may be large, moderate in size, or small.** Regardless of cell size, the **nuclei are relatively large and may be vesicular with nucleoli** (Fig. 20-39A), **or they may be hyperchromatic and irregular or angular in configuration with nucleoli that are less conspicuous** (Fig. 20-39C). The cytology in bronchial secretions is similar to sputum and typically diagnostic of adenocarcinoma, although not usually organ specific (Fig. 20-39D). **A feature of small-cell mammary carcinoma, usually lobular carcinoma, is the arrangement of tumor cells in single file** (Indian file) (Fig. 20-39C). In some cases of metastatic lobular carcinoma, the cancer cells are miniature signet ring cells, with a mucus vacuole in the center of the cell pushing the nucleus to one side. Other small-cell cancers can mimic this pattern, notably SSC of lung (see Chap. 29).

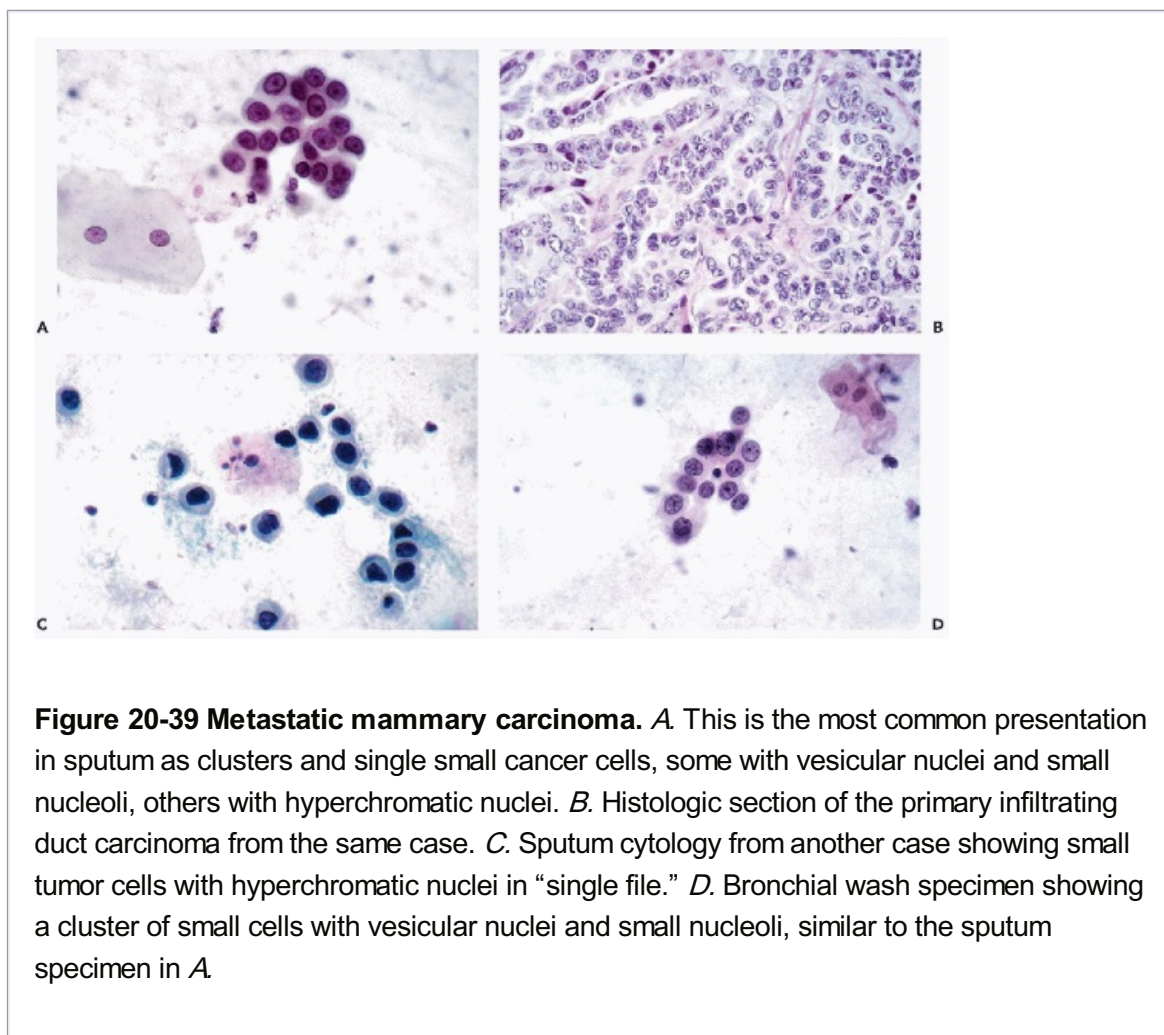

Figure 20-39 Metastatic mammary carcinoma. *A.* This is the most common presentation in sputum as clusters and single small cancer cells, some with vesicular nuclei and small nucleoli, others with hyperchromatic nuclei. *B.* Histologic section of the primary infiltrating duct carcinoma from the same case. *C.* Sputum cytology from another case showing small tumor cells with hyperchromatic nuclei in “single file.” *D.* Bronchial wash specimen showing a cluster of small cells with vesicular nuclei and small nucleoli, similar to the sputum specimen in *A.*

The cells from rare cases of metastatic carcinoma of male breast are identical to those derived

from duct carcinomas of female breast.

Clinical history is paramount in the diagnosis of metastatic mammary carcinoma. If confirmatory evidence is desired, it may be of help to stain for cytoplasmic mucin and to demonstrate estrogen receptor expression by immunocytochemistry,

P.697

although neither is specific whether present or absent. For further discussion of metastatic mammary carcinoma, see Chapter 26.

Kidney

Metastatic renal carcinoma may be observed in patients with an occult primary tumor. Until the recent almost routine use of CT and ultrasound examinations of patients with vague abdominal symptoms small, asymptomatic renal carcinomas escaped detection and as many as **one-third of renal cortical carcinomas were first diagnosed in a metastatic site**. Many still are. **The tumor cells contain abundant cytoplasmic lipid, accounting for the classical clear cell appearance of the tumor** (Fig. 20-40A). **The cytologic diagnosis is suggested by cancer cells with large vesicular nuclei and prominent nucleoli, with abundant clear or faintly staining delicate cytoplasm**. Often, the fragile cytoplasm is lost as the tumor cells are aspirated or exfoliated, and the cells present as bare nuclei or with only wisps of cytoplasm. They may be single or in small clusters (Fig. 20-40B).

Although this classical presentation is commonly observed, renal cancer may exhibit diverse other cytologic patterns, including cells with granular eosinophilic cytoplasm, or elongated or **spindly cancer cells mimicking sarcoma** (Fig. 20-40C). In such cases, positive **immunostaining for keratins and vimentin** is often helpful, as this combination of staining is observed in few other tumors.

Figure 20-40 Metastatic renal cortical carcinoma. *A.* Primary renal carcinoma showing the typical highly vascularized tumor composed of large cells with clear cytoplasm. *B.* FNA of tumor metastatic to the lung, yielding cells with large, round or oval vesicular nuclei with small nucleoli. The delicate cytoplasm is stripped away, leaving only a few adherent wisps of cytoplasmic material. *C.* Not uncommonly, the cells of renal cortical carcinoma have

granular, eosinophilic cytoplasm, and may be spindly or sarcomatoid.

Urothelial Carcinoma

Metastatic urothelial carcinomas can rarely be identified as to site of origin. We have seen cases in which the needle aspirate yielded **tumor cells similar to umbrella cells**, for example, **large, flat, mononuclear or multinuclear crescent-shaped cells**, with a thick, refractile cell border corresponding to the asymmetric unit membrane (see Chap. 22) (Fig. 20-41A). We have not observed such cells in other metastatic tumors. More commonly, however, the aspirate contains nondescript epithelial tumor cells, or spindly, columnar or cuboidal cells (Fig. 20-41B). In exceptional cases, the FNA of a lung metastasis may have a remarkable resemblance to fragments of low-grade papillary urothelial tumors of the bladder (see Chap. 23).

Some observers report **cercariform cells** to be diagnostic of metastatic urothelial cancer in aspirates (FNA). The cells are described as cancer cells with exceptionally long cytoplasmic processes that have a bulbous or flattened end (Powers and Elbadawi, 1995; Renshaw and Madge, 1997; Hida and Gupta, 1999). Although we have observed elongated cancer cells in aspirates of well-differentiated metastatic urothelial carcinomas (Fig. 20-41), we do not consider them to be specific. **Antibody to uroplakin** has been shown to specifically recognize metastatic urothelial cancer in tissues and in circulating blood (Moll et al, 1995; Wu et al, 1998; Li et al, 1999).

Renshaw et al (1997) investigated the frequency of small cells with **eosinophilic cytoplasmic inclusions** in pulmonary

P.698

effusions and concluded that **such cells are more common in the presence of metastatic urothelial carcinoma than in lung cancer**. As discussed in Chapter 22, the inclusions are composed of cytoplasmic filaments in cells undergoing degeneration, and are very common in benign urothelial cells in the urinary sediment. Their alleged association with metastatic urothelial cancer is puzzling and awaits confirmation and evaluation.

Figure 20-41 Metastatic urothelial carcinoma. *A.* A finding of umbrella cells shown here is unusual but strongly suggestive of urothelial carcinoma. *B.* More commonly, the aspirate will contain spindly and columnar or cuboidal epithelial cancer cells.

Malignant Melanoma

Metastatic melanomas may mimic all types of malignant tumors and present considerable difficulties in diagnosis, particularly in patients whose primary tumor is either unknown or was treated many years before as a "benign nevus." Metastatic melanoma in the lung **usually sheds nonpigmented cancer cells** and in the absence of clinical history, they are seldom specifically identified. The diagnosis of metastatic malignant melanoma may be suspected, however, if the **cells have very large nucleoli and/or intranuclear inclusions of invaginated cytoplasm (nuclear holes)**. If the cancer cells are large and contain the **fine, dusty brown pigment of melanin**, a definitive diagnosis of melanoma can be established (Fig. 20-42). It is important to remember, however, that in patients with **disseminated melanoma and sometimes in heavily suntanned individuals**, the **alveolar macrophages may contain phagocytized melanin**, usually seen as a **very fine yellowish brown coloration of the cytoplasm**; and the sputum may contain **macrophages with engulfed pigment that must not be confused with pigmented melanoma cells**. The differential diagnosis of pigments commonly present in macrophages is discussed in Chapter 19. If the nucleus is obscured by what is believed to be melanin, the pigment should be removed by bleaching and the slide restained to permit evaluation of the suspect cells. The **cells of melanoma are usually larger than pigment-containing macrophages, and they exhibit the nuclear abnormalities of cancer cells**. If material is available for a cell block, immunostaining with the antibody to pre-melanosomes (HMB-45 or Melan-A) will be positive in most melanoma cells and negative in macrophages. The antibody to S-100 protein is more sensitive but less specific, and is most useful if negative. Metastatic melanoma should always be included in the differential diagnosis of metastatic malignant tumors of unknown primary site.

Figure 20-42 Metastatic malignant melanoma in sputum. Large nucleoli and fine cytoplasmic pigment are strongly suggestive, if not diagnostic of melanoma. (*B*: oil immersion.)

P.699

Pancreatic Islet Cell Tumor

We have encountered one case of metastatic pancreatic islet cell tumor in an FNA of lung from a 75-year-old man. The tumor cells formed loosely cohesive, flat clusters of uniform cells with eccentrically placed nuclei, occasional giant nuclei, and a moderate amount of cytoplasm (Fig. 20-43). Not surprisingly, the cytology was indistinguishable from that of a carcinoid tumor (see

Tumors with Psammoma Bodies

Concentrically laminated, calcified psammoma bodies may be observed in specimens of sputum, bronchial aspirates, or FNA cytology. Their interpretation depends on the company they keep. If the calcified bodies are not accompanied by cancer cells, the **possibility of a primary calcific process in the lung** (pulmonary alveolar microlithiasis, pneumoliths) must be considered (see Chap. 19). Once this has been ruled out by the presence of suspicious or frankly malignant cells accompanying the psammomas, the relationship of the cells to the calcific deposits is of diagnostic importance.

- The most common source of cancer cells with psammomas in sputum is **papillary bronchioloalveolar or adenocarcinoma** of lung. The psammomas may be separate or **only loosely related to moderate-size cancer cells** (see Fig. 20-12D).
- If the psammomas lie **within clusters of obvious, large cancer cells**, metastatic **ovarian** or, much less likely, endometrial or tubal carcinomas must be considered. In most such cases, before there are lung metastases, there is clinical evidence of a pelvic mass or intra-abdominal metastases with ascites.
- If the psammomas are integrated within clusters of smaller, generally uniform and innocuous-appearing cancer cells, metastatic **thyroid carcinoma** is a strong possibility. One should search for tumor cells with nuclear creases or intranuclear cytoplasmic inclusions (see Chap. 30).

Figure 20-43 Metastatic pancreatic islet cell tumor. FNA of the pulmonary metastasis yielded flat clusters of uniform cells of "plasmocytoid" configuration indistinguishable from carcinoid tumor. The presence of an occasional cell with a larger nucleus is not unusual.

Rare examples of other tumors associated with psammoma bodies have been reported, including **metastatic breast cancer with giant cells** (Ludwig and Gero, 1987), and **metastatic ameloblastoma** (Levine et al, 1981). We have also observed **psammoma bodies**

in **mesothelioma**, usually in effusions or needle aspirates of tumor (see Chap. 26).

Metastatic Carcinomas, Not Further Specified

Most metastatic carcinomas occur as single cells or in clusters with no specific cytologic features for assigning tumor type or organ of origin. One can only make an educated guess based on clinical and radiologic findings, age, gender, etc. Papillary groups of tumor cells with vacuolated cytoplasm that are readily identified as adenocarcinoma may originate from metastatic carcinomas of the breast, prostate, pancreas, bowel, stomach or endometrium, and often cannot be differentiated from primary bronchogenic adenocarcinomas.

P.700

The problem of metastatic squamous carcinoma in the lung is even more vexing because it is much less common than metastatic adenocarcinoma, and the tumor cells cannot be differentiated from those of a primary squamous lung cancer. Thus, cells from **metastatic squamous carcinomas of the esophagus, the buccal cavity or larynx, and even the uterine cervix may all look alike**, and in the absence of accurate clinical information, one may erroneously assume that they are derived from a primary bronchogenic carcinoma. On the other hand, the history of a treated carcinoma of another organ does not rule out the possibility of a second primary bronchogenic carcinoma.

The cytologic diagnosis of a new primary lung cancer should be favored in patients with a past history of carcinoma of different histologic and cytologic type. For example, the diagnosis of lung cancer would be favored in a patient with a history of adenocarcinoma who now has squamous cancer cells in a cytologic specimen, or vice versa. A word of caution is indicated here: **cells originating from metastatic cancers of any type may appear eosinophilic in exfoliated material because of poor preservation. Thus, cytoplasmic eosinophilia of a few poorly preserved cells is not a sufficient criterion to label cancer cells as squamous.**

Special stains are sometimes of help in classification of a metastatic tumor. Examples are the immunocytochemical demonstration of **thyroglobulin in thyroid carcinoma; calretinin for mesothelioma; cytokeratin and vimentin to distinguish epithelial from non-epithelial tumors (except that renal carcinoma and mesothelioma may contain both); prostate-specific antigen or prostatic acid phosphatase in prostatic cancer; HMB-45, Melan-A, and S-100 in malignant melanoma; alkaline phosphatase in the case of osteogenic sarcoma; estrogen or progesterone receptor expression in breast cancer; and lymphocyte common antigen (CD-45) for lymphoid cells.** None of these are entirely specific, and must be interpreted with consideration of cytologic morphology and clinical context. Among the more useful conventional special stains **is mucicarmine staining for identification of mucin-secreting adenocarcinoma.** Unfortunately, there is rarely enough material in difficult cases to carry out the battery of special stains and immunocytochemical reactions that are possible with histologic specimens. In fortuitous cases, a cell block may be available for such studies.

Figure 20-44 Metastatic sarcomatoid squamous carcinoma. *A,B.* FNA of pulmonary metastasis from sarcomatoid squamous carcinoma of the esophagus in a 48-year-old man. *C.* Biopsy of sarcomatoid carcinoma of esophagus in the same case. (*A:* Diff-Quik stain; *B:* Papanicolaou stain.)

Metastatic Sarcomas

Metastatic sarcomas are much less common than metastatic carcinomas, but more common than primary sarcomas of lung. Ali et al (1998) reported making the diagnosis of metastatic leiomyosarcoma by cytologic examination of sputum but, except for such rare examples (see below), the **sarcomas are best sampled by percutaneous needle aspiration** (Kim et al, 1986). Even with adequate sampling, **specific classification of a metastatic sarcoma, or differentiation from sarcomatoid carcinoma** (Fig. 20-44A-C) **may not be possible without the primary tumor for comparison.** Hajdu and Koss (1969) and Hajdu and Hajdu (1975)

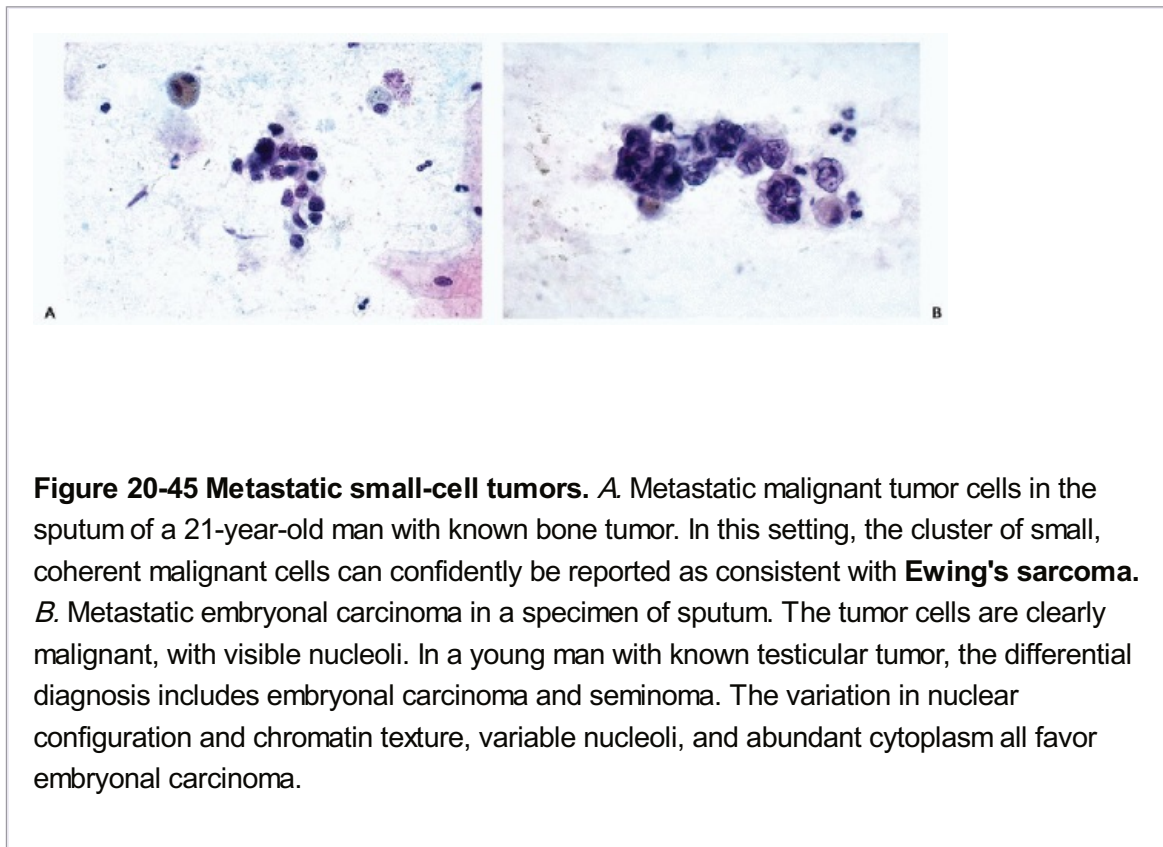

P.701

pointed out that spindly tumor cells are shed by some metastatic sarcomas, whereas others, and particularly embryonal rhabdomyosarcomas, may be remarkably pleomorphic. We have not always been able to classify the pulmonary metastases of solid small-cell malignant tumors of childhood. Nor have we often been successful, for example, in the search for striations in known cases of metastatic rhabdomyosarcoma. However, **it is possible to make an educated guess of tumor type based on cytologic pattern with knowledge of the patient's age and clinical and radiologic findings (see below).**

Publications within the last several years have included reports of needle aspirates of metastatic **epithelioid sarcoma** (Niemann and Bottles, 1993), **chondrosarcoma** (Abdul-Karim et al, 1993), **synovial sarcoma** (Costa et al, 1997; Silverman et al, 2000), **Ewing's sarcoma** (Collins et al, 1998), **osteosarcoma** (Nicol et al, 1998) and **alveolar soft part sarcoma** (Logrono et al, 1999). We have observed metastatic Ewing's sarcoma (Fig. 20-45A) and metastatic testicular embryonal carcinoma (Fig. 20-45B) in sputum cytology specimens. Koss previously illustrated a multinucleated tumor cell of metastatic testicular choriocarcinoma in

sputum (1992).

Criteria for the cytologic diagnosis and classification of metastatic sarcoma are not different from those of primary sarcoma. In most cases, the primary site and type of tumor are already known when needle aspiration of a clinically suspected metastasis is performed, usually to confirm the clinical diagnosis and exclude an incidental benign neoplasm, or to rule out an inflammatory process that may be a consequence of therapy. Caution is indicated before making a diagnosis on very scanty evidence, or if cytologic morphology is not consistent with the clinical setting. **In the final analysis, knowledge of the clinical history and review and comparison of the cytologic findings with histologic sections of a previously removed or biopsied cancer is key to the identification and classification of many metastatic tumors.**

Malignant Lymphomas Secondarily Involving Lung

Non-Hodgkin's Lymphoma

Lymphomas of all types may make their appearance in sputum or bronchial aspirates. As already noted, **well-differentiated small-cell lymphoma/chronic lymphocytic leukemia (SCL/CLL) presents as single or loosely aggregated small lymphocytes that differ little from normal lymphocytes** (Fig. 20-46A). They may exhibit slight variability in size, minimal granularity of nuclei, and sometimes slight hyperchromasia or visible nucleoli, but these are subtle differences. **Also subtle, but of diagnostic value, the cells of SCL/CLL are much more uniform than those of nonneoplastic lymphoid tissue; they do not show the variability and variety of cell types that constitute the pattern of cells from inflammatory processes or hyperplastic lymphoid tissue that may be dislodged from tonsillar tissue or lymphoid nodules in the bronchial wall.**

Large-cell lymphomas shed cells that are more easily recognized as lymphoma. They are most readily diagnosed in FNA specimens in which they comprise a single population of cells that contrasts with the mixed population of reactive lymphoid tissue. **The cells are twice the size of mature lymphocytes, or larger, and in the case of large-cell anaplastic (K1) lymphomas, they may be as large as small-cell (oat cell) carcinoma or some soft tissue sarcomas, or even larger.** On occasion, they may be mistaken for anaplastic carcinoma, even in histologic section. As in effusions, they have nuclei that are irregularly round or ovoid with nuclear protrusions, indentations and folds, and finely textured or vesicular nuclei, many with prominent nucleoli (Fig. 20-46B,C). The cells are often stripped of their delicate cytoplasm, and it is useful to search for cytoplasmic fragments (**lymphoglandular bodies**) in the background of the smear (Fig. 20-46C). Since primary carcinomas of the lung may occur in patients with a past history of lymphoma, the differential diagnosis with small-cell (oat

P.702

cell) carcinoma is of particular importance, especially if sampling is scanty (see above for a discussion of the distinguishing features of SSC versus lymphoma).

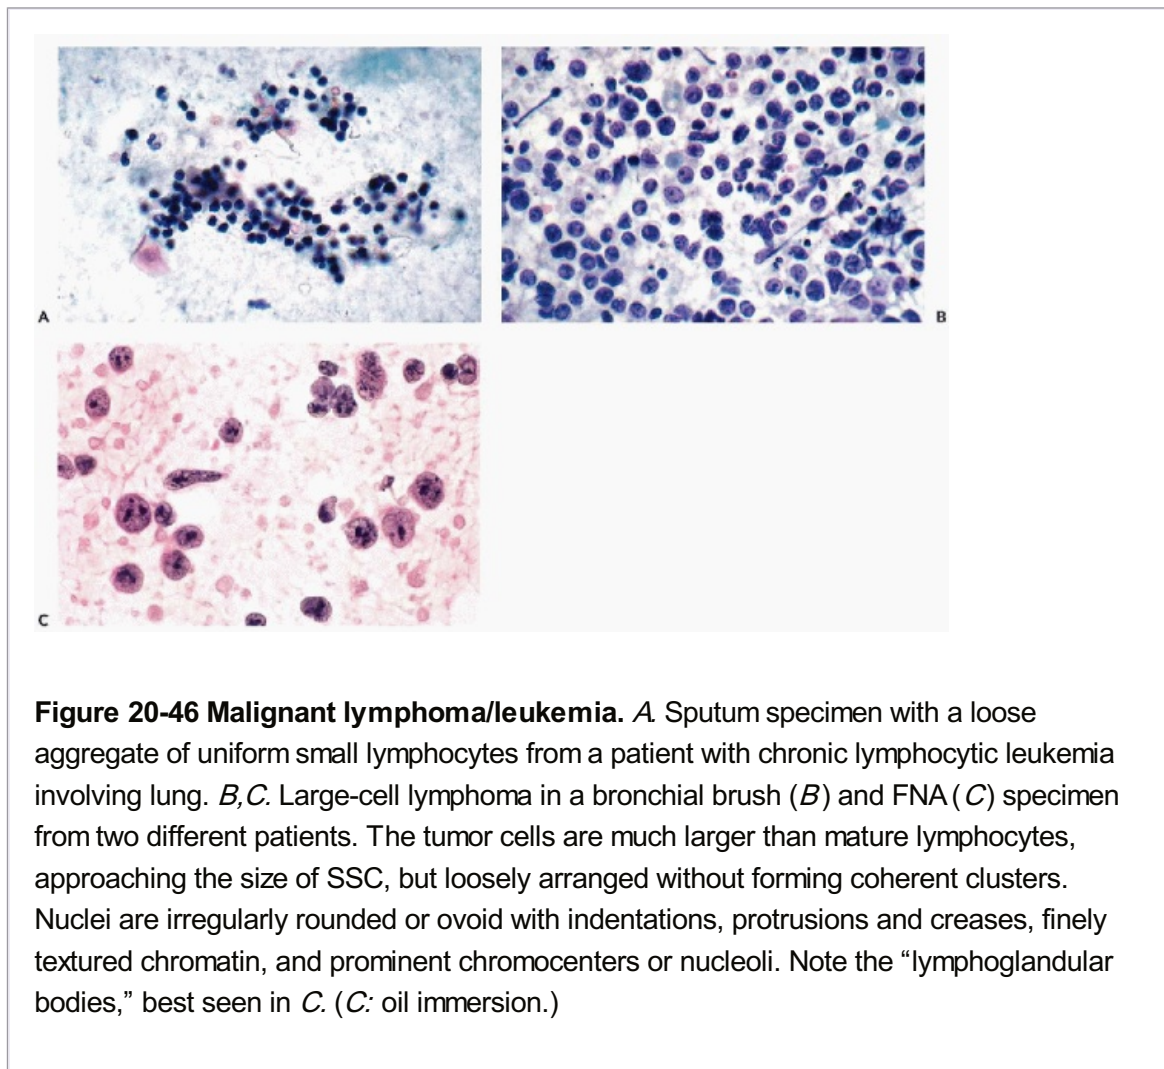

Figure 20-46 Malignant lymphoma/leukemia. *A.* Sputum specimen with a loose aggregate of uniform small lymphocytes from a patient with chronic lymphocytic leukemia involving lung. *B,C.* Large-cell lymphoma in a bronchial brush (*B*) and FNA (*C*) specimen from two different patients. The tumor cells are much larger than mature lymphocytes, approaching the size of SSC, but loosely arranged without forming coherent clusters. Nuclei are irregularly rounded or ovoid with indentations, protrusions and creases, finely textured chromatin, and prominent chromocenters or nucleoli. Note the “lymphoglandular bodies,” best seen in *C*. (*C*: oil immersion.)

Hodgkin's Disease

In a review of the cytology of sputum and bronchial lavage specimens from patients with Hodgkin's disease involving the lung (Suprun and Koss, 1964), **mono- and binucleated cells were observed that had prominent nuclei and large eosinophilic nucleoli.** The resemblance to classic binucleated Reed-Sternberg cells was striking (Fig. 20-47A,B). Yet even

in those cases, **in the absence of a clinical history, differentiation from other types of cancer was tentative at best.** The difficulty was compounded in patients with a history of prior radiotherapy to the mediastinum, in whom the resulting cellular atypia with marked nuclear pyknosis and often striking cytoplasmic eosinophilia made cell classification very difficult.

In most cases, only rare single tumor cells are found in sputum of patients with Hodgkin's disease but, on rare occasions, we have seen Reed-Sternberg cells within groups of tumor cells resembling those of large-cell lymphoma (Fig. 20-47B).

P.703

Others who have described tumor cells of Hodgkin's disease in cytology specimens include Reale et al (1983) who reported six cases and Fullmer and Morris (1972) who were able to establish the diagnosis of mediastinal Hodgkin's disease by sputum cytology. Levij (1972) described a patient with **cavitary** Hodgkin's disease in the lung diagnosed by cytology. More recently, Sharma et al (1986), Bardales et al (1996) and Stanley et al (1993) reported additional cases of Hodgkin's disease with lung involvement.

Mycosis Fungoides

In **disseminated mycosis fungoides, a T-cell lymphoma of skin, pulmonary involvement** is common and the cytologic diagnosis of malignant lymphoma has been made in bronchial brushings (Ludwig and Balachandran, 1983) and in sputum (Rosen et al, 1984; Shaheen and Oertel, 1984). The diagnosis of lung involvement by mycosis fungoides can be made only in patients with known cutaneous disease, in whom **small or large mononuclear lymphoid cells with cerebriform nuclei** are found in company of atypical lymphocytic cells (see also Chap. 34).

Primary Pulmonary Thymoma

These rare intrapulmonary tumors have been observed in percutaneous aspiration biopsies, and the aspirates may be confused with large-cell lymphoma (Fig. 20-48). They are similar to primary thymomas of mediastinum, described in Chapter 37.

Plasmacytoma (Plasma Cell Myeloma, Multiple Myeloma)

Plasma cell tumors have been described in needle aspirates of various organs and in effusions, but rarely in sputum or bronchial aspirates. Geisinger et al (1986) reported one such case among 126 patients studied. The diagnosis is made on finding an increased number of **plasma cells with atypical and immature forms in sputum or bronchial specimens** of patients known to have disseminated plasmacytoma and suspected of lung involvement clinically or radiologically. In some cases, the aspirate may contain lymphoid blast cells that suggest lymphoma but not necessarily plasmacytoma. Before making the diagnosis of plasma cell myeloma on a needle aspirate of an infiltrate in the lung that is rich in plasma cells, one would have to consider plasma cell granuloma (a pseudotumor with plasma cells) and other chronic inflammatory processes in the differential diagnosis (see Chap. 19).

**Leukemia**

Leukemic cells in blastic phase may occasionally be identified in sputum. This finding can be of assistance in evaluating the clinical status of the patient and in planning therapy. The cytology is not unlike that of non-Hodgkin's lymphoma (see also Chap. 26).

Microvascular Cytology

An interesting technique for sampling and identifying the cancer cells in cases of lymphangitic spread of metastatic cancer was proposed by Masson et al (1989). They reported finding cancer cells in blood samples obtained by wedged pulmonary artery catheter and examined by cytologic techniques. Success was claimed in seven of eight patients (see also Chap. 30 for comments on cancer cells in the blood).

Accuracy of Pulmonary Cytology**Principal Sources of Error in the Diagnosis of Bronchogenic Carcinoma**

Careful collection and processing of cytology specimens and close correlation with clinicoradiologic imaging is absolutely necessary if one is to achieve optimum diagnostic results. In general, a false-positive diagnosis is more serious an error than a false-negative diagnosis, and Tables 20-7, 20-8, and 20-9 list the principal sources of such errors. Above all, inconsistencies between clinical findings and cytologic diagnosis must not be allowed to go

TABLE 20-7 PRINCIPAL SOURCES OF ERROR IN THE CYTOLOGIC DIAGNOSIS OF PRIMARY SQUAMOUS LUNG CANCER

Sources of Error	Helpful Diagnostic Features
Irradiation effect on benign squamous cells	History of radiation; bizarre enlarged cells, smudgy nuclei, vacuoles, multinucleation
Tracheitis sicca	Permanent tracheostomy; abnormal squamous cells from near stoma in cough specimen or aspirate; not in bronchial specimen
Atypical squamous metaplasia	Atypical cells in clusters, no single cells. Often after mechanically assisted respiration (ARDS)
Cancer chemotherapy (particularly Myleran)	History of chemotherapy, primarily for leukemia or organ transplant. Cellular changes often bizarre. May be seen in children on chemotherapy.
Mycetoma with atypical squamous metaplasia	Presence of fungus. X-ray shows cavity with "fungus ball."
Vegetable cells; pollen	Thick refractile cell wall, characteristic morphology, yellow pigment
Mucoepidermoid carcinoma	A rare tumor arising in major bronchi; abnormal squamous cells accompanied by mucus-secreting glandular cells
Metastatic squamous carcinoma	History of cancer, radiologic findings
Upper respiratory tract carcinoma	Cancer cells in sputum, not in bronchial specimens; negative chest x-ray; origin located by careful exam of upper respiratory mucosa and scrape cytology or biopsy of suspicious lesions

TABLE 20-8 PRINCIPAL SOURCES OF ERROR IN THE CYTOLOGIC DIAGNOSIS OF ADENOCARCINOMA OF LUNG

Sources of Error	Helpful Diagnostic Features
Papillary fragments of hyperplastic bronchial epithelium ("Creola" bodies)	Presence of goblet cells within the papillary fragments of bronchial epithelium. Cilia or terminal plates of surface epithelium. History of asthma, bronchiectasis.
Atypical bronchial cells; cytomegaly, karyomegaly	Presence of cilia or terminal plates; cells often retain columnar or cuboidal shape
Numerous goblet cells misinterpreted as mucinous adenocarcinoma	Retained columnar shape, small basal nuclei. History of asthma, chronic bronchitis.
Post-bronchoscopy bronchial cell atypia	Bronchial cells with hyperchromatic nuclei; columnar shape, terminal bar (cilia lost). History of recent bronchoscopy.
Atypical pneumocytes, type II	History of acute febrile respiratory illness, with persisting symptoms. May occur in pulmonary infarct and some chronic pulmonary disorders. Atypia is usually transitory.
Viral cytopathic changes	Familiarity with cytopathic effects of cytomegalovirus, herpesvirus, respiratory syncytial virus, adenovirus.
Reactive mesothelium	Present only in percutaneous needle aspirates. Flat sheets of epithelial cells with prominent nucleoli; intercellular "windows."
Pemphigus	Correlate with clinical history of painful mucosal and cutaneous blisters.
Mucoepidermoid carcinoma	A rare tumor, arising from major bronchi. Presence of mucus-secreting glandular cells accompanied by atypical squamous cells.
Metastatic adenocarcinoma	History. Radiologic evidence of multiple tumors.

TABLE 20-9 PRINCIPAL SOURCES OF ERROR IN THE CYTOLOGIC DIAGNOSIS OF SMALL CELL CARCINOMA OF LUNG

Sources of Error	Helpful Diagnostic Features
Reserve (basal) cell hyperplasia	Compact clusters of uniform small cells. No single cells, no molding. No nuclear smudging or necrosis. Often a straight edge to the cluster.
Pools of lymphocytes	Small mature lymphocytes singly and in loose aggregates, mixed with monocytes and reactive or immature lymphocytes that have nucleoli. No coherent groups of cells. No molding, nuclear smudging or necrosis.
Small-cell adenocarcinoma	Overlapping groups and single cancer cells with smoothly configured round or ovoid vesicular nuclei and nucleoli. No molding. No nuclear smudging. May have mucin vacuoles.
Lymphoma	Single cells and loose clusters of noncoherent cells. Nuclei show protrusions and invaginations. Visible and often prominent nucleoli. Lymphoglandular bodies and micronuclei (apoptotic bodies).
Carcinoid	Uniform cells in coherent flat groups with uniform, regular nuclei. "Salt and pepper" chromatin. No necrosis. Present only in bronchial brush or FNA specimens.
Small "blue cell" tumors: Ewing's tumor; Wilms tumor; neuroblastoma; embryonal rhabdomyosarcoma; pleuropulmonary blastoma	Tumors primarily of children and adolescents. May be mistaken for lymphoma but form coherent clusters.
Droplets of condensed mucus	Smooth, round, "ink drop" appearance with no chromatin structure. Usually single.

Sputum

In data from early studies still valid today, positive identification of lung cancer in good sputum samples from an unselected series of patients with the disease was in the range of 60% to 70%

(Koss et al, 1964; Johnston, 1982; Pilotti et al, 1982; Ng and Horak, 1983; Rosenthal, 1988). Cancer cells exfoliate intermittently, and the number of positive diagnoses achieved in a single sample may be increased by as much as 10% with three or more samples over a period of several days. As was discussed earlier, the highest diagnostic yield is with squamous carcinomas arising in lobar or segmental bronchi, whereas relatively few peripheral adenocarcinomas shed cells into the sputum until they grow large enough to break into a sizable bronchus.

Bronchial Secretions

Atay and Brandt (1975) studied this in great detail. Of the 885 patients with bronchogenic carcinoma that they examined, 79% of the patients with centrally located tumors and 45% with peripheral tumors had positive cytology in bronchial secretions. Using the TNM clinical classification system (see p 647), these investigators documented increasing efficiency of cytologic diagnosis with increasing tumor size: from 30% for smaller, localized tumors to a maximum of 62% to 65% for larger, more extensive tumors (T3, T4). There was also increased diagnostic yield from tumors with more extensive metastases, ranging from 49% for N0 tumors (no lymph node metastases) to 72% for tumors with extensive nodal and other metastases (N3, M1). Biopsy diagnoses, as well, are generally easier to obtain from the more advanced tumors.

Fiberoptic Bronchoscopy and Brushing

The rigid bronchoscope has now been superseded by fiberoptic bronchoscopy, permitting visualization and cytologic sampling of third and fourth order bronchial branches. Solomon et al (1974) obtained positive cytologic diagnoses by fiberoptic bronchoscopic brushing in 41 of 46 patients with bronchogenic carcinoma. In a study of 224 patients, Bibbo et al (1973) reported positive diagnoses in 60% of primary peripheral adenocarcinomas and 81% of peripheral squamous carcinomas of lung by fiberoptic bronchial brushing, compared with fewer than 20% by sputum. Interestingly, an additional 12% of patients had positive sputum after the bronchial brushing. Thus, the superiority of fiberoptic bronchial brushing for cytologic diagnosis of peripheral lung cancers, as originally described by Hattori et al (1964, 1971), was firmly established soon after its introduction. In a further advantage, the brushings provide bronchopulmonary samples for microbiologic studies that may contribute to the diagnosis of inflammatory disease in distal portions of the lung.

Needle Aspirates

Beginning with major reviews of results by Dahlgren and Nordenström (1966) and Dahlgren and Lind (1972), percutaneous needle aspiration cytology of primary lung cancers has been widely accepted as an accurate diagnostic method, and this technique greatly increased the number

P.706

of small peripheral lung tumors that could be diagnosed by cytology. The cell sample must be technically adequate, representative of the disease, and properly identified as to its source and clinical setting. Under these conditions, a positive diagnosis based on adequate sampling and reported by an experienced examiner should be comparable to a biopsy. Still, erroneous positive cytologic diagnoses of lung cancer (false-positive cases) do occur, even under the best of circumstances. In a College of American Pathologists (CAP) report of data from 436 institutions in North America, there were 0.8% false-positive diagnoses, that is, 8 per 1,000; the false-negative rate was ten times higher, 8% (Zarbo and Fenoglio-Preiser, 1992). Some of the

principal causes of diagnostic error, discussed in this chapter, include chronic lung disease with proliferation of bronchioloalveolar lining epithelium and reactive proliferation of mesothelium that may be observed in needle aspirates. Errors can be minimized, and the effect on patient care lessened by close communication between pathologist, radiologist and surgeon or pulmonologist, and by confirming the cytologic diagnosis with biopsy or frozen section at the time of thoracotomy. Confirmation is especially important when the diagnosis is based on scanty evidence or if cytologic findings are inconsistent with the clinical or radiologic diagnosis.

Many benign lesions can be identified in adequately sampled cases, including some of the benign tumors described above, inflammatory lesions discussed in this chapter and Chapter 19, and especially certain infectious processes. Still, a report of "negative for malignant cells," with or without some specific diagnosis, does not necessarily exclude a coexisting cancer that may be present in an adjacent, unsampled area. Zakowski et al (1992) attributed the relatively poor negative predictive value of needle aspirates (53%) to inaccurate or inadequate sampling of many cases. They recommended that scanty or insufficient specimens be reported as such, and not as negative. We agree with this recommendation. On the other hand, a positive diagnosis based on adequate sampling and reported by a competent observer should have the same accuracy as a tissue biopsy.

In summary, it should be emphasized that only by combined judicious use of all three methods of diagnosis (i.e., radiography, bronchoscopy, and cytology) can optimal diagnostic results be achieved.

ACKNOWLEDGMENTS

Thanks are due to my colleagues Dr. L. G. Koss and Dr. M. B. Zaman, who provided many of the illustrations for this chapter and Chapter 19.

Epithelial Lesions of the Oral Cavity, Larynx, Trachea, Nasopharynx, and Paranasal Sinuses

HISTOLOGIC RECALL

As briefly described in Chapter 19, the **oral cavity** (including the palate, tongue, pharynx, and floor of the mouth) is lined by **squamous epithelium with varying degrees of**

P.714

surface keratinization. The **surface of the larynx**, facing the oral cavity, is also lined by **squamous epithelium.** The **inner aspects of the larynx** (including the vocal cords) are lined by a **nonkeratinizing epithelium composed of five to six layers of parabasal and intermediate squamous cells.** **Lower aspects of the larynx** and the adjacent **trachea** are, in part, lined by similar **nonkeratinizing epithelium** and, in part, **by ciliated epithelium, identical to bronchial epithelium,** described in Chapter 19. The **paranasal sinuses and the nasopharynx** are principally lined by an epithelium composed of cuboidal and columnar ciliated cells. **All ciliated epithelia contain mucus-producing goblet cells and may undergo squamous metaplasia,** as described in Chapter 19.

Minor salivary glands are dispersed throughout the oral cavity and adjacent organs. The tumors of these glands can be sampled only by aspiration biopsy. Aspiration biopsy may also be used for the study of deeply seated tumors of the various component organs and bony structures (Castelli et al, 1993; Das et al, 1993; Gunhan et al, 1993; Mondal and Raychoudhuri, 1993; Mathew et al, 1997; Domanski and Akerman, 1998; Shah et al, 2000). These issues are discussed in Chapters 32 and 36.

ORAL CAVITY

SAMPLING TECHNIQUES

Lesions of the oral cavity **can be sampled by smears obtained by scraping.** In most cases, the scrape smears may be obtained with a simple tongue depressor or a small curette. For oral lesions covered with **thick layers of keratin,** a more vigorous scraping with a **sharp metallic instrument may be advisable.** A brush specifically designed to sample oral lesions was described by Sciubba (1999).

Figure 21-1 Normal cells in oral scrapings. *A.* Scrape smear of labial fold of lower lip. The squamous cell shows a nuclear bar with lateral extensions (caterpillar nuclei) similar to Anitschkow cells. *B.* Anucleated squamous cell from the palate. (*A:* High magnification.)

INDICATIONS FOR CYTOLOGIC EXAMINATION

The principal application of cytologic techniques to epithelial lesions of the oral cavity is the diagnosis of occult carcinomas, not identified or not suspected on clinical inspection. As will be set forth in this chapter, cytologic methods are particularly valuable in screening for occult oral cancer, but may occasionally contribute to the diagnosis of early or unsuspected cancers of adjacent organs. King (1962) briefly summarized the early history of the application of cytologic techniques to lesions of the oral cavity.

CYTOLOGY OF ORAL SQUAMOUS EPITHELIUM IN THE ABSENCE OF DISEASE

Squamous Epithelial Cells

Normal squamous epithelium of the oral cavity sheds **superficial and intermediate squamous cells**, identical to squamous cells of the vagina and cervix, except that nuclear pyknosis is not observed. Such cells occur either singly or in clusters and are identical with squamous cells that are found in specimens of sputum and of saliva (see Chap. 19).

A longitudinal condensation of the nuclear chromatin in the form of a nuclear bar with lateral extensions, similar to that observed in **Anitschkow cells in the myocardium** in rheumatic heart disease, has been recorded in superficial squamous cells by Wood et al (1975). A similar cell change was also illustrated in the *Atlas of Oral Cytology* by Medak et al (1970). Such cells are commonly seen in smears of the **mucosal surface of the lower lip and the adjacent floor of the mouth** in perfectly healthy people (Fig. 21-1A). The change is probably related to “nuclear creases” but its significance is unknown. Similar cells may be observed in mesothelial cells in the pericardium surface of the conjunctiva and in other organs.

P.715

Fully keratinized squamous superficial cells without visible nuclei (keratinized squames) are a common component of oral smears, especially from the palate, and do not necessarily reflect a significant abnormality (Fig. 21-1B). All stages of transition between nonkeratinized and keratinized cells may be observed. Smaller **parabasal squamous cells** may be observed if the surface of the epithelium is vigorously scraped, or if an epithelial defect, such as an ulceration, is present.

In general, the cytology of the oral cavity in the absence of disease is simple and monotonous.

Squamous oral cells carry on their membranes **blood group antigens** (for review, see Dabelsteen et al, 1974).

Other Cells

Mucus-producing columnar cells originating in the **nasopharynx or the salivary gland ducts** may occasionally be observed. A vigorous scrape of the **tonsillar area** or the **base of the tongue** may result in **shedding of lymphocytes**, singly or in clusters.

Oral Flora

Oral flora, especially in patients with poor oral hygiene, is rich in a variety of saprophytic fungi and bacteria. A protozoon, *Entamoeba gingivalis*, is fairly common (Fig. 21-2A). It is a multinucleated organism larger than *Amoeba histolytica*, from which it differs because it does not phagocytize red blood cells (see Chaps. 10 and 24). The presence of these organisms does not necessarily indicate an inflammatory process in the oral cavity. An unusual organism, *Simonsiella* species, was described in smears of oropharynx, sputum, and gastric aspirates by Greenebaum et al (1988). The large bacteria form caterpillar-like chains, each composed of 10 to 12 individual bacteria. The bacterial chains are readily observed overlying squamous cells (Fig. 21-2B). The organism is nonpathogenic, most likely to be observed in mouths of people with rich dietary intake, particularly fat and proteins.

Figure 21-2 Microorganisms in oral smears. A. *Entamoeba gingivalis*, a common inhabitant of the buccal cavity. B,C. *Simonsiella* organism. Note the caterpillar-like appearance of the bacterium in C. (A,B: Pap stain; C: Methylene blue; A,C: Oil immersion.)

Buccal Squamous Cells in Genetic Counseling and as a Source of DNA

Buccal smears are the cheapest and easiest-to-use laboratory test to determine genetic sex, by observing and counting **sex chromatin (Barr bodies)** in **squamous oral cells**. The

Barr bodies can be recognized as a **half-moon shaped chromatin condensation at the nuclear membrane** (see Chaps. 4, 7, 8, 11, and 29). Although, theoretically, in genetic females all squamous cells with nonpyknotic, open vesicular nuclei should contain a Barr body, in practice, it can be identified in fewer than half of these cells by light microscopy of oral smears stained with Papanicolaou's stain. Further, peripherally placed **chromocenters** and **focal thickening of the nuclear membrane may mimic Barr bodies**. There is some controversy about whether the frequency of

P.716

visible sex chromatin varies during the menstrual cycle (Chu et al, 1969; Ashkenazi et al, 1975).

For all practical intents and purposes, the finding of **about half a dozen or more cells** with a clear-cut single sex chromatin body is **diagnostic of the XX female chromosomal constitution** (see Chap. 4). An **excess of Barr bodies** (very rarely more than two in a cell) indicates an excess of X chromosomes ("superfemale," with cells containing 47 chromosomes with XXX). Occasionally, **malignant cells may contain two or more Barr bodies**, reflecting aneuploidy.

The presence of **Barr bodies in cells in a phenotypic male strongly suggests Klinefelter's syndrome** (47 chromosomes, YXX). **The absence of Barr bodies in a phenotypic female** suggests **Turner's syndrome** or another form of gonadal dysgenesis (see Chap. 9).

Buccal cells collected in mouthwash or by other techniques may be valuable as **a source of DNA** for various tests, including person identification (Heath et al, 2001).

INFLAMMATORY DISORDERS

Acute and Chronic Inflammatory Processes

Superficial **erosion or ulceration** of the squamous epithelium occurs frequently in the course of diffuse or localized inflammatory processes or poor oral hygiene. As a result, the normal population of superficial and intermediate squamous cells in smears is partially or completely replaced by **parabasal squamous cells** from the deeper epithelial layers. Such cells **may vary in size and shape**; their principal feature is relatively **large, occasionally multiple, round or oval vesicular nuclei** of monotonous sizes. As is common in nuclei of younger cells, **chromocenters** may be readily observed against a pale nuclear background; occasionally, **small nucleoli** may be noted. The cytoplasm is often poorly preserved (Fig. 21-3). In the presence of a **diffuse stomatitis or gingivitis**, the preponderance of the irregularly shaped parabasal cells may result in an initial impression of a significant epithelial abnormality; close attention to nuclear detail will prevent an erroneous diagnosis of cancer.

In chronic ulcerative processes, **mono- and multinucleated macrophages** may also occur. Purulent exudate or **leukocytes** of various types are a common component of smears in these situations. **Plasma cells** are frequently observed, particularly in smears from the posterior oral cavity or pharynx.

Specific Inflammatory Disorders

Actinomycosis

As discussed in Chapter 19, bacteria of the *Actinomyces* species are **common saprophytes** of the oral cavity, usually found within tonsillar crypts. They may be acquired by chewing on

bacterium-carrying plants, and are usually of no clinical significance. However, they may invade the traumatized or ulcerated mucosa and form an abscess or sinus tract. As discussed in Chapters 10 and 19, the organism can be recognized in Papanicolaou-stained oral smears as masses of matted bacterial filaments. The identity of the organism should be confirmed by culture if there is clinical evidence of an inflammatory process. **The presence of *Actinomyces* in oral smears must always be correlated with clinical findings to distinguish between saprophytic and pathogenic organisms.**

Oral Herpes

This common disorder, characterized by blisters and painful ulcerations, is caused by Herpesvirus type 1 that can be identified by the **characteristic nuclear changes** described and illustrated in Chapters 10 and 19. Kobayashi et al (1998) observed the pathognomonic cell changes in smears of only 4 of 11 patients in whom the diagnosis could be confirmed by culture and, in some cases, by in situ hybridization.

Moniliasis (Thrush)

Clinically, moniliasis forms a characteristic white coating of the oral cavity. This organism may be identified with ease by finding the characteristic fungal spores and pseudohyphae (see Chap. 10). This harmless infection, previously occurring mainly in debilitated patients and diabetics, has been recognized as **one of the first manifestations of the acquired immunodeficiency syndrome (AIDS).**

Blastomycosis

Sivieri de Araujo et al (2001) described the application of oral smears for diagnosis of **Paracoccidiomycosis (South American blastomycosis)**, a common and serious disorder in Latin American countries. The yeast form is described in Chapter 19.

CHANGES IN ORAL SQUAMOUS CELLS IN DEFICIENCY DISEASES

In diseases associated with **deficiencies in vitamin B₁₂ and in folic acid, such as pernicious anemia**, the squamous cells of the oral mucosa may show significant **enlargement of both the nucleus and the cytoplasm** (Graham and Rheault, 1954; Massey and Rubin, 1954; Boen, 1957). Similar changes may be observed in the related disorder, **megaloblastic anemia** (Boddington and Spriggs, 1959), and in **tropical sprue** (Staats et al, 1965). The findings were documented by comparison with normal cell populations and are statistically impressive. Vitamin B₁₂ and folic acid are essential for DNA synthesis. If there is an insufficient supply of either factor, the DNA synthesis becomes disturbed, with resulting cell enlargement (Beck, 1964). There is evidence that this change is not confined to the oral epithelium but may affect many tissues (Foroozan and Trier, 1967). In reference to the uterine cervix, the changes were discussed in Chapter 17. For changes in the gastrointestinal tract, see Chapter 24.

Figure 21-3 Inflammatory changes in squamous cells of buccal epithelium; buccal scrape smears. *A.* The cytoplasm is poorly preserved. A multinucleated cell may be noted. *B, C.* There is considerable variation in cell sizes, but the nuclei are, on the whole, uniform, an important diagnostic feature. Note chromocenters. Some of the dark-staining nuclei are showing early pyknosis. *D.* Histologic section of ulcerative gingivitis. Inflammatory changes in buccal epithelium. (Case courtesy of Dr. Sigmund Stahl, New York, NY.)

In my own experience, the oral smears from **patients with a variety of disorders**, probably having **malnutrition as a common denominator**, may occasionally have a population of large squamous cells with vesicular nuclei and numerous chromocenters. The finding should lead to a hematologic work-up of the patients. A marked enlargement of squamous cells may also be caused by **radiotherapy** (see below).

Nieburgs described nuclear enlargement and “discontinuous nuclear membrane” in buccal squamous cells in 72% of patients with cancer. He considered this **malignancy associated change (MAC)** as reflecting “an altered mitotic function of cells.” Some of Nieburgs' material was air-dried and the observations may be an artifact. The specific association of the buccal cell changes with cancer remains unproven. For further comments on MAC, see Chapter 7.

Heavy keratin formation on the surface of oral epithelium is a common phenomenon occurring at the line of teeth occlusion, the palate, parts of gingiva, and occasionally elsewhere. The **milky white appearance** of such areas is

best classified clinically as leukoplakia and appears histologically as a benign squamous epithelium, topped with layers of keratin. This **benign disorder** must be differentiated from **precancerous leukoplakia, which may have a similar clinical appearance. The differences are based on cytologic and histologic features**, discussed in detail below.

“Hairy” Oral Leukoplakia

This is a benign lesion characteristically located on the **lateral aspect of the tongue** that was first observed in **AIDS patients**. The lesion shows vacuolization (ballooning) of squamous cells and intranuclear inclusions. The lesion was shown to be associated with **Epstein-Barr virus** (EBV) (Greenspan et al, 1986). There is no information on the cytologic presentation of this uncommon lesion.

1237 / 3276

Darier-White's Disease (Keratosis Follicularis)

Darier-White's disease is primarily a **chronic, benign, hereditary skin disease** presenting as small pink papules that may become confluent. The **oral mucosa may be involved** and show a rough pebbly surface or verrucous plaques. **Histologically**, the disease is characterized by the formation of slits or spaces within the epidermis and by **disturbances of keratinization** referred to as “**corps ronds**” (round bodies) and “**grains**.” The corps ronds are miniature epithelial pearls, often containing a single large cell with a degenerated nucleus in the center. The grains are elongated, prematurely keratinized cells.

According to Witkop et al (1961), **smears from oral lesions of Darier's disease** show **parabasal squamous cells with numerous chromocenters**, corresponding to the cells lining the intraepithelial slits. Cells containing **round cytoplasmic eosinophilic inclusions**, probably corresponding to premature keratinization, may be observed. The **corps ronds** appear in smears as **epithelial pearls**—a simple one consists of a single keratinized cell within a cell; in more elaborate arrangements several keratinized cells may be found in the center of the pearl (Fig. 21-4A). The **grains** correspond to single, heavily keratinized, elongated cells.

P.719

Burlakow et al (1969) also pointed out that squamous cells scraped from the oral lesions may remain attached to each other by one end, not unlike leaves attached to the branch of a tree. The “**leafing out**” pattern associated with “corps ronds” and “grains” was considered by these authors as **diagnostic of this disorder**.

Hereditary Benign Intraepithelial Dyskeratosis (Witkop)

In this rare hereditary disorder, there is formation of **white spongy folds and plaques** of thickened mucosa within the oral cavity. The bulbar conjunctiva and the cornea may also be involved. The **histologic findings** in the oral epithelium disclose a marked **epithelial hyperplasia** accompanied by a **disorder of keratinization** in the form of pearl formation, which is not unlike the corps ronds of Darier's disease (Fig. 21-4B). In smears from such lesions, one sees **keratinized squamous cells** with elongated, dense nuclei and “**pearls**” composed of a large, orange-staining central degenerated cell, surrounded by a halo and an outer elongated cell with a preserved sickle-shaped nucleus (Fig. 21-4A). **Scrapings from the eye** in these patients showed identical cells. Witkop et al (1960, 1961) suggested that this cytologic presentation is diagnostic of this uncommon disorder.

White Sponge Nevus of Cannon

In this exceedingly uncommon hereditary disorder, there is a **spongy hypertrophy of squamous epithelium involving the oral, vaginal, and anal mucosa**. Abnormal keratinization may be noted. In cytologic preparations, **intracytoplasmic eosinophilic inclusions** may be observed (Witkop et al, 1960). A case of this rare entity was reported by Morris et al (1988). Electron microscopic investigation of the cytoplasmic “inclusions” disclosed bundles of “tonofilaments” of unspecified diameter, most likely representing keratin filaments, in keeping with Witkop's suggestion.

VESICLE- OR BULLAE-FORMING CONDITIONS

In a number of pathologic conditions, most of which can be diagnosed clinically, **liquid-filled blisters (vesicles) or large bullae may occur within the oral cavity**. As a general rule, the

vesicles or bullae break down, and **the resulting ulcerations may become the subject of a cytologic scrutiny. One such condition is herpes simplex** of the oral cavity, which was discussed above.

With rare exceptions, the vesicle-forming disorders are manifestations of dermatologic disease and the involvement of the oral cavity is usually secondary. The most important such disorders are **erythema multiforme** and **various forms of pemphigus** (Wu et al, 2000). Specialized sources should be consulted for a detailed description and classification of these diseases.

Although **erythema multiforme** can affect the mucosa of the mouth, the diagnosis is usually based on clinical examination. There is no information on cytologic features of this transient disease, which is characterized by red plaques and small vesicles involving the skin. On the other hand, the nearly uniformly fatal **pemphigus vulgaris may have its primary manifestations in the oral cavity.**

Pemphigus Vulgaris

As has been discussed in Chapter 17, the disease is caused by **antibodies to desmoglein 3, a component protein of desmosomes, causing a disruption of desmosomes in the lower layers of the squamous epithelium**, leading to the formation of fluid-filled blisters, vesicles or bullae (Fig. 21-4D). The latter contain the atypical **cells of Tzanck**, which can be observed in smears of broken vesicles. The Tzanck cells are **squamous cells with frayed cytoplasm**, approximately of the size of large parabasal cells, occurring singly and in clusters. Occasionally, these cells show **cytoplasmic extensions. The most important feature of these cells is the presence of large, clear nuclei containing conspicuous large nucleoli that are usually single but may be multiple** (Fig. 21-4C). **These cells may be readily mistaken for cells of an adenocarcinoma.** "Cell-in-cell" arrangements, similar to those in epithelial "pearls" may be occasionally observed. **Multinucleated macrophages** may be observed in smears of treated pemphigus (Medak et al, 1970).

As a consequence of the autoimmune events, the **cells shed from pemphigus are coated with immunoglobulins.** Decker et al (1972), Lascaris (1981), and several other observers have documented, by **immunofluorescence**, the presence of coating immunoglobulins in smears from pemphigus. Faravelli et al (1984) used IgG peroxidase-antiperoxidase reaction to provide a permanent record of the immunoglobulin coat on the surfaces of acantholytic cells in smears of oral pemphigus. Harris and Mihm (1979) provided a summary of the immunologic differential diagnoses between pemphigus and other bullous lesions of the oral cavity. A current summary of the immunologic events leading to pemphigus vulgaris and related disorders may be found in an editorial by Bhattacharya and Templeton (2000). Takahashi et al (1998) reported a case wherein there was **simultaneous presence of herpes simplex and of pemphigus** in the oral cavity, both reflected in the oral smear.

Other skin diseases, too numerous to describe within the frame of this work, may involve the oral mucosa. Because the dermatologic features overshadow the oral presentation, there is no information on cytologic abnormalities in these disorders.

CHANGES CAUSED BY THERAPY

Changes in oral epithelial cells caused by **radiation therapy** were studied by Zimmer in my laboratory (unpublished)

P.720

and by Umiker (1965). The changes are similar to those observed and described for the uterine

cervix and consist of **marked enlargement** of squamous cells and their nuclei (see Chap. 18). They may occur either as a result of administration of the radiated beam **directly to the oral cavity or to adjacent organs, such as the neck**.

Bhattathiri et al (1998) studied the **response of cells of squamous carcinoma** of the oral cavity to radiation and reported that the **nuclear abnormalities are radiation dose related**. As has been described in Chapter 18, the response of oral squamous epithelium to small doses of radiation was used as an index to gauge the response of squamous cancer of the uterine cervix to radiotherapy.

Changes caused by **chemotherapy** were observed by Witkop (1962). He noted nuclear degeneration and “cell-within-cell” structures following treatment with **methotrexate** and other anticancer chemotherapeutic agents. **Severe stomatitis**, caused by excessive shedding and ulceration of the buccal epithelium, is a common complication of treatment with various chemotherapeutic agents.

MALIGNANT LESIONS

Invasive Squamous Carcinoma and Its Precursors

Risk Factors

Abuse of **tobacco and alcohol** are the key epidemiologic factors in patients developing cancer of the oral cavity and the larynx. Tobacco in any form, such as pipe-, cigar-, or cigarette smoking, reverse smokers (people holding the burning end of a cigarette in their mouth), betel-nut chewers (tobacco powder is often wrapped inside the betel leaf) represent high-risk populations. The latter two forms of tobacco use are seen mainly in India and other parts of Southeast Asia. It is not known why alcohol abuse contributes to oral carcinogenesis. In the United States, African-Americans appear to have a higher risk of oral squamous cancer than people of other ethnic backgrounds (Skarsgard et al, 2000).

The presence of **human papillomavirus (HPV)** in oral cancer has been suspected for some years (Syrjänen, 1987) and has now been documented in benign and malignant lesions of the oral cavity. Garelick and Taichman (1991) observed HPV types 2, 4, 6, 11, 13, and 32 in the benign lesions, including leukoplakia, and HPV types 16 and 18 in oral carcinomas. Paz et al (1997) observed HPV sequences in only 15% of squamous cancers of the esophagus and the head and neck area. HPV was mainly observed in tumors of the tonsillar area and in some metastases. The presence of HPV had no prognostic significance. Mork et al (2001) considered infection with HPV type 16 as a risk factor in squamous cancer of the head and neck. These authors suggested oral sex as a possible source of virus. El-Mofty and Lu (2003) reported the presence of HPV type 16 only in **squamous carcinoma of the palatine tonsil** and considered this disease to be a distinct entity in patients age 40 or younger.

Clinical Aspects and Histology

Invasive squamous carcinoma is the most common malignant lesion of the oral cavity. The disease may occur in the epithelium of the **mouth, tongue, cheek, palate, tonsils, and pharynx**. Most patients with invasive squamous carcinomas show **ulcerative lesions with indurated borders** that are easily identified as cancer on clinical inspection. Rarely, inflammatory processes may imitate ulcerative oral cancer. However, some oral carcinomas, when first observed, **are not ulcerated**. Some of these lesions may have **wart-like**

configurations (verrucous carcinomas) and others may present as **areas of redness (erythroplakia) or as white patches with irregular borders**, somewhat similar in appearance to benign **leukoplakia**. A biopsy confirmation of the nature of the disease is always recommended.

The invasive squamous cancers can be **graded**, with **well-differentiated, keratin-producing cancers, including verrucous lesions, classified as grade I, poorly differentiated carcinomas composed of small cells as grade III. The intermediate grade II, characterized by medium-size cells showing squamous differentiation, is by far the most common**. Except for verrucous carcinomas, which usually have a fairly good prognosis, grading has limited prognostic value. The **size and the depth of invasion of the primary tumor (stage)** is a more important prognostic factor. Stage I lesions are limited in size and depth of invasion. Stage IV lesions are cancers with distant metastases, usually to lymph nodes of the neck, which must be evaluated prior to therapy. Surgical treatment of oral cancers is often disfiguring and debilitating, whereas radiotherapy and chemotherapy are not always effective. **The 5-year survival of about 60% for stage I disease and less than 20% for stage IV, is not satisfactory** (Shah, 1992; Skarsgard et al, 2000; Charabi et al, 2000).

Forastiere et al (2001) summarized the sequence of molecular events leading to the occurrence and progression of squamous cancer of the head and neck area. The most common molecular event is a **mutation of p53 gene** that may occur even in relatively minor epithelial changes, classified as “dysplasia” (see below).

Cytology

In most cases, the diagnosis of invasive squamous cancer of the oral cavity is established by biopsy of clinically suspicious lesions. It has become apparent, however, during a large study of oral cancer detection (see below) that many dentists who are in the best position to see the abnormalities, often do not recognize the malignant nature of very early carcinomas. If given an opportunity to sample such questionable lesions by a painless and bloodless cytologic procedure, they may choose to do so, whereas they may be reluctant to recommend a biopsy.

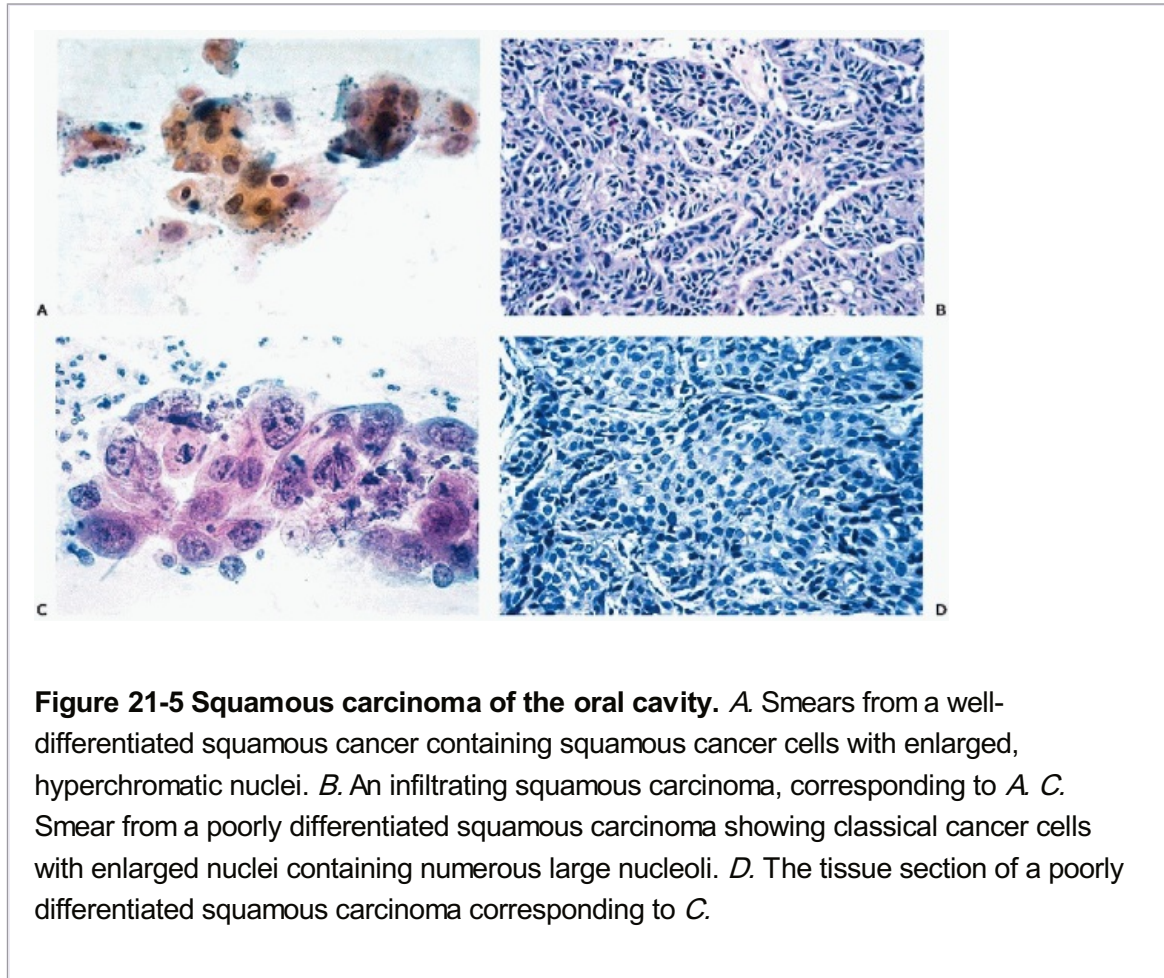

The cytologic diagnosis of ulcerated invasive lesions is relatively simple **if care has been taken to remove the layer of necrotic surface material prior to cytologic sampling**. Regardless of the type of tumor, the smear background nearly always shows necrotic material, blood, and numerous leukocytes.

P.721

Cytologic preparations closely reflect the degree of keratinization of the lesion. In **heavily keratinized squamous cancer**, the cancer cells are characterized by **orange- and yellow-staining cytoplasm and large, sometimes pyknotic, dark-staining irregular nuclei** (Fig. 21-5A,B). **“Ghost” cells**, with heavily keratinized cytoplasm and virtually no residual nuclear material, are frequent, as are **keratinized “pearls” of malignant cells**. In **nonulcerated, invasive, keratinizing carcinomas**, particularly the **verrucous type**, the cytologic diagnosis of cancer may be **obscured by abundant, fully keratinized “ghost” cells, without perceptible nuclear abnormalities**. Reddy and Kameswari (1974) studied 165 patients with keratinizing carcinoma of the hard palate in reverse smokers in India and were able to reach the diagnosis in only 60% of the patients. Similar results were reported by Bănóczy and Rigó (1976). **In such cases, close attention must be paid to relatively minor nuclear abnormalities, which may occur in only a few cells; nuclear enlargement and irregularity of outline, with or without nuclear hyperchromasia, are of diagnostic**

significance. In case of doubt, a biopsy should be recommended.

In **poorly differentiated squamous carcinomas**, the cytoplasmic keratinization is not prominent, but the **nuclear abnormalities, such as large nucleoli and a coarse pattern of chromatin distribution**, are evident (Fig. 21-5C,D). In the latter form of oral cancer, **the nucleocytoplasmic ratio is usually modified in favor of the nucleus, a feature not always observed in the cells of the keratinizing variety.** To anyone familiar with the principles of cytologic diagnosis of cancer, the diagnosis of invasive squamous carcinoma of the oral cavity will cause little difficulty if the potential pitfalls discussed above are considered.

PRECURSOR LESIONS OF SQUAMOUS CANCER

Because of poor results of treatment of invasive squamous carcinoma, the discovery of precursor lesions may prove to be lifesaving. **Precancerous lesions of the squamous epithelium of origin** must invariably precede invasive cancer.

Clinical Presentation and Histology

On clinical inspection, there are two types of precancerous lesions in the oral cavity:

P.722

- **The common white lesions** with irregular, jagged borders, usually referred to as precancerous leukoplakias, are clinically similar to the benign leukoplakias, and correspond to precancerous lesions with a heavily keratinized surface and nuclear abnormalities in well-differentiated squamous cells (Fig. 21-6). The white color of the lesion is caused by the opaque surface layer of keratinized epithelium. The term mild or moderate dysplasia is often

attached to such lesions.

- **The less common red lesions (erythroplakia)**, corresponding to the nonkeratinizing precursor epithelial lesions, are usually composed of smaller cancer cells with minimal or absent keratinization of surface (carcinomas in situ or severe dysplasia) (Fig. 21-7). The red color is due to the vascularized stroma underlying the often thin epithelium. The lesion is a definitive precursor of invasive squamous cancer and has been so recognized in the studies by Sandler (1962, 1963), Shafer et al (1975), and Mashberg et al (1977). Niebel and Chomet (1964) proposed in vivo staining of the oral mucosa with toluidine blue to demarcate the territories of these lesions.
- **In some fortuitous cases**, incidentally discovered, there are no visible oral lesions. Acetowhite areas, after application of 3% acetic acid solutions, may be observed in such patients (Fig. 21-8).

Subdø et al (2001) studied the **DNA content** of oral biopsies as a **prognostic marker in oral keratinizing lesions (leukoplakia)** that were either **histologically benign or atypical ("dysplasia")**. Of the 45 patients with histologically benign leukoplakia, 5 (11%) developed squamous carcinoma after a follow-up period of 5 years or more. Four of the 5 patients had an abnormal (aneuploid) DNA pattern. Only 1 patient with normal (diploid) DNA pattern developed oral cancer. Of the 150 patients with histologic atypia or dysplasia, 36 (24%) developed invasive cancer after a follow-up ranging from 4 to 57 months, mean 35 months. With only 3 exceptions, all cancers developed in patients with abnormal (tetraploid or aneuploid) DNA patterns. Lippman and Hong (2001) enthusiastically supported the conclusions of this work, which suggests that detectable and measurable nuclear abnormalities, as previously reported by Califano et al (2000), may be of practical use in assessing the behavior of oral leukoplakia.

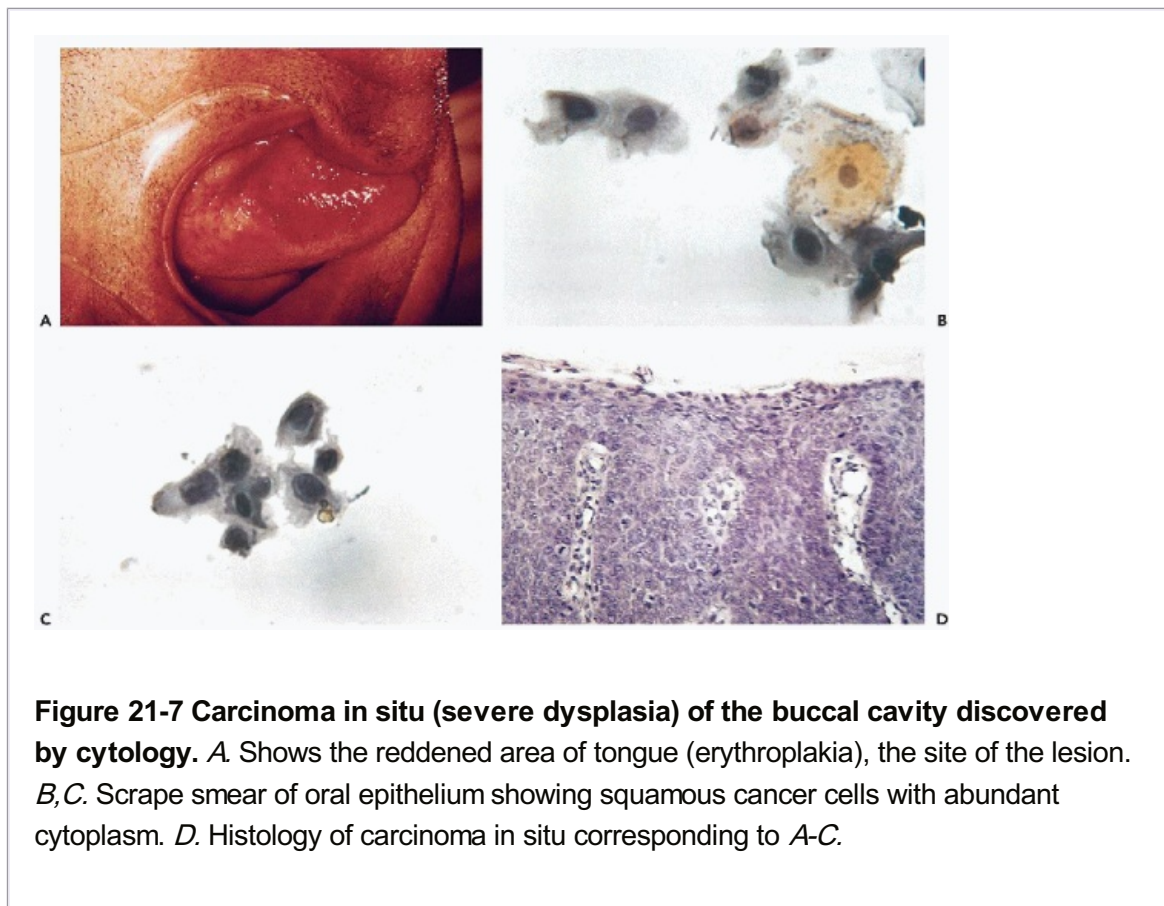

Figure 21-6 Atypical leukoplakia (moderate dysplasia) of oral cavity. *A* Clinical appearance of the white lesion with jagged edges. *B*. The keratinizing lesion of the oral epithelium with scattered nuclear abnormalities. Note marked inflammatory infiltrate in the stroma. *C*. Atypical squamous cells with an enlarged hyperchromatic nucleus in oral smear.

Subbø et al (2002) also followed 37 patients with “**erythroplakia**” for a median observation time of 53 months. There were 12 patients with normal (diploid) DNA distribution and none of them developed invasive cancer after a median follow-up period of 98 months. On the other hand, 23 of 25 patients with aberrant DNA content developed invasive squamous cancer. The histologic grade of the lesion, sex of patients, and use of tobacco were not significant as prognostic factors.

Although the red oral lesions progress to cancer with a much higher frequency than white lesions, this study strongly suggests that a stratification of these lesions is possible by relatively simple image analysis of the DNA content. For further comments on DNA measurement techniques, see Chapters 46 and 47.

P.723

Cytology

Keratinizing Lesions (Precancerous Leukoplakia, Mild or Moderate Dysplasia)

The accurate cytologic diagnosis of **keratinizing carcinoma in situ** or of **precancerous leukoplakia** may prove difficult, particularly if abnormal cells in smears are overshadowed by keratinized benign cells or anucleated squames. However, after **thorough screening** of cytologic material, it is rare not to find at least a **few cells suggesting** either a **borderline squamous lesion** or a **well-differentiated squamous cancer with keratinized cytoplasm and nuclear enlargement** (see Fig. 21-6C). In these situations, knowledge of the clinical presentation of the lesion is invaluable and should lead to a **confirmatory biopsy**, even though the cytologic evidence may be very scanty.

Hong et al (1986) reported that oral administration of 13-*cis*-retinoic acid had a beneficial effect

on the size and degree of cellular abnormalities in oral precancerous leukoplakias of some patients, but had fairly severe toxic effects.

Nonkeratinizing Lesions (Carcinoma In Situ, Severe Dysplasia)

The terms **oral carcinoma in situ or severe dysplasia**, as distinct from precancerous leukoplakia, refers to malignant epithelial lesions without significant keratin formation on their surfaces. As mentioned above, nearly all of these lesions present **clinically as areas of redness (erythroplakia)** but may be **clinically occult**.

Scrape smears from such lesions are characterized by a mixture of malignant **well-differentiated parabasal or intermediate squamous cells**, with translucent cytoplasm and **significant nuclear enlargement and hyperchromasia** (see Figs. 21-7 and 21-8). The term **dyskaryosis**, or “**dysplastic cells**,” used in the discussion of precursor lesions of carcinoma of the uterine cervix is applicable here (see Chap. 11). It is not uncommon to observe in such smears a few **squamous cancer cells with markedly keratinized cytoplasm and marked nuclear abnormality**. On the whole, the smear pattern in oral carcinoma in situ is remarkably similar to that of a high-grade squamous precursor lesion of carcinoma of the uterine cervix of well-differentiated type. These observations were confirmed in the study of carcinoma in situ recurring after treatment of invasive oral cancer (see below).

Stahl et al (1964), in discussing the implications of dyskaryosis in oral mucosal lesions, pointed out the necessity of long-term follow-up of patients showing such cells in their smears. The same authors noted that experimentally induced cancer of the cheek pouch of the hamster is also heralded by the appearance of dyskaryotic cells.

P.724

There was no invasion.

RESULTS OF CYTOLOGIC SCREENING FOR OCCULT CARCINOMA AND PRECURSOR LESIONS

The difficulty of clinical identification of precancerous leukoplakia and carcinoma in situ, both easily curable precursor stages of oral cancer, was not fully appreciated until an extensive cytologic study of mouth lesions was conducted by the Veterans Administration, guided by the late Dr. H. Sandler (Sandler, 1962; Sandler et al, 1963). As a consultant, I (LGK) was privileged to review a major portion of the material resulting from this study. There were 2,758 patients with visible mouth lesions screened by cytology, and there were 287 histologically documented cases of invasive carcinoma. Many of these lesions were very small (26 were less than 1 cm in diameter, and 69 were less than 2 cm in diameter); many were not ulcerated, not indurated, and not fixed to the underlying tissue. **Eighty three of these lesions (approximately 29%) were not recognized clinically as cancers** by the examining dentists.

There were also 28 patients with squamous carcinoma in situ. Only 11 of the lesions were suspected of being cancer by the examining dentists, whereas 17 **(about two-thirds) were considered benign**. Thirteen lesions were **reddish in color**, 6 were white, and the rest were of various colors; only 6 were ulcerated and only 5 indurated. **Thus, redness of circumscribed areas of oral epithelium erythroplakia is frequently characteristic of carcinoma in situ** (see Fig. 21-7A).

The comparison of Sandler's data with observations on a nonscreened population surveyed by Shafer (1975) is enlightening. Shafer reviewed the clinical and histologic data on 82 oral carcinomas in situ (including 16 lesions of the lip), diagnosed by biopsy only. While in Sandler's survey, 28 carcinomas in situ were found in 2,758 patients with visible mouth lesions (1%), in Shafer's survey, there were 66 oral carcinomas in situ in 45,702 histologic accessions (0.0014%). It may be argued that the two populations of patients were unequal. Sandler's patients were men, mainly older than 50 years of age, many among them drinkers and smokers, who were much more prone to oral cancer than Shafer's unselected population. Nevertheless, Sandler's rate of discovery of carcinoma in situ was 10 times higher than in Shafer's population. The comparison of clinical findings is also enlightening; roughly one-half of Sandler's lesions were red, whereas there were only 16% of such lesions in Shafer's survey, strongly suggesting that **even the most competent observers consider red oral lesions as benign and do not perform biopsies. Such lesions should be the prime target for cytologic screening.**

A survey by Stahl et al (1967) confirmed that cytologic screening for oral cancer is feasible. Practicing dentists in

P.725

the area of New York City were instructed to obtain **smears from all visible abnormalities of the oral cavity**. Although only a small proportion of the invited dentists responded, 47 oral cancers were found in 2,297 patients examined. Eleven of the 47 cancers (24%) were clinically unsuspected, thus confirming the results of the Veterans Administration study quoted above. It does not appear feasible or reasonable to cytologically screen all dental patients. However, a **scrape smear of an oral lesion may well permit more conservative surgery for earlier lesions and may be lifesaving**. Shiboski et al (2000) recently emphasized a major deficiency in the professional and public education regarding early diagnosis of oral cancer.

Sandler's, Shafer's, and Mashberg and Meyer's studies pointed out that the **floor of the mouth was the most frequently affected site of oral squamous cancer**, followed by lateral surface of **tongue** and **soft palate**. These should be the areas of the oral cavity that deserve a

careful inspection during routine dental examination.

Within recent years, there has been a revival of interest in cytologic detection of oral cancers in the United States, based on evaluation of oral smears by a semiautomated cell analysis system **OralCDx** (Sciubba, 1999). A specially designed brush was used to secure cell samples from the visible lesions of the oral cavity. Of the 945 lesions sampled by cytology, 131 (about 14%) were biopsy-confirmed “dysplastic” lesions or carcinomas. In these cases, the smears were judged to be either “positive” or “atypical.” In 29 patients (22% of the biopsy-documented lesions), **the malignant nature of the lesion was not suspected clinically**, a result remarkably similar to the Stahl (1967) study cited above. The histologic findings in these patients have not been reviewed by independent observers and, thus, it is not possible to determine how many of the “dysplasias” were truly precancerous lesions.

In situations in which an exceptionally high risk of oral cancer exists, more extensive surveys may be justified. Wahi, from Agra, India, demonstrated the value of cytologic techniques among **betel-nut chewers**, who have a very high incidence of oral carcinoma. His results (personal communication, 1966) are summarized in Table 21-1. The data strongly suggest that high-risk candidates for oral cancer, such as tobacco chewers and heavy cigar- and pipe smokers, represent a primary target for screening for oral cancer by cytologic techniques.

CYTOLOGIC DIAGNOSIS OF RECURRENT ORAL CANCER AFTER TREATMENT

Local recurrences of oral cancer after treatment by surgery, radiation, or a combination of these two techniques are sufficiently common to warrant a close follow-up of all patients. The **possibility of a residual or second primary cancer within the same anatomic area** is also very high in treated patients. **There is excellent evidence that the addition of cytologic techniques to the follow-up examination may result in the diagnosis of a recurrent or new cancer before it is suspected clinically.**

TABLE 21-1 CYTOLOGIC DIAGNOSIS OF ORAL CARCINOMA AMONG BETEL-NUT CHEWERS	
Total cases of oral cancer studied	812
Clinically unsuspected	69
(66 squamous carcinoma, 2 reticulum cell sarcoma, 1 adenocarcinoma)	
Clinical diagnoses on 69 unsuspected cases

Malignant cells	39
Cells suggestive of cancer	21
Dyskaryotic cells, possibly malignant	9
(Prof. P.N. Wahi, Agra, India, personal communication.)	

Umiker (1965) reported on four such cases following radiation treatment. Hutter and Gerold (1966) applied cytologic techniques in the follow-up of patients previously treated by surgery. In limiting the application of cytology to the patients *without* visible lesions, they uncovered clinically unsuspected recurrent cancer in 10 of 177 patients investigated (6%). These authors were using material scraped from the general area of prior surgery by an endometrial curette. The results are summarized in Table 21-2.

An interesting aspect of Hutter and Gerold's work concerns the time that elapsed between the cytologic evidence of recurrent carcinoma and the appearance of a clinical abnormality, however slight, amenable to a biopsy. In several of the cases, 4 to 6 months of follow-up by a very experienced observer were required to see a lesion, usually an area of redness or a whitish patch. In six of the eight patients with cytologic diagnosis of recurrent carcinoma, the major histologic component of the lesion was a carcinoma in situ, either with or without superficial infiltration. In this work, the degree of accuracy of cytologic identification of carcinoma in situ was extremely high and is summarized in Table 21-3.

This work, as well as the results of cancer detection surveys described above, strongly suggest that the **silent stage of carcinoma in situ, whether primary or recurrent, is not readily identifiable clinically and precedes invasive squamous carcinoma of the oral cavity.** This stage of cancer may last for several months, and possibly much longer, before producing a visible lesion. Carcinoma in situ may be accurately identifiable by cytology, as is the case with many other organs discussed in this book.

OTHER TUMORS

Besides squamous carcinoma, other benign or malignant tumors involving the oral cavity may occasionally be diagnosed

P.726

by smear. We have observed cases of a **benign mixed tumor** of salivary glands and of **adenoid cystic carcinoma**, located in the palate, and diagnosed on scrape smears. For description of these tumors, see Chapter 32. We have also seen a case of **primary malignant melanoma** of the oral mucosa. The smears were characterized by the presence of obvious malignant cells and macrophages containing melanin pigment (Fig. 21-9). King (1962) reported several examples of cytologic findings in a few uncommon tumors, such as an ulcerating

osteosarcoma of the jaw, two **malignant lymphomas** (one of palate and one of mandible), and a case of **ulcerating adenoid cystic carcinoma**. A number of observers used aspiration biopsies (FNAs) to investigate the nature of palpable tumors of the oral cavity (Castelli et al, 1993; Das et al, 1993; Gunhan et al, 1993; Mondan and Raychoudhuri, 1993; Mathew et al, 1997; Damanski and Åkerman, 1998; Shah et al, 1999). Most lesions examined were **tumors of the salivary glands, dental anlage tumors, and tumors of the jaws**, topics that are discussed in Chapters 32 and 36. Of note were several cases of **malignant lymphomas**, involving the base of the tongue and the tonsils and several **metastatic carcinomas**. We have also observed a case of **lymphoblastic leukemia** in a child recognized on a scrape smear of an oral lesion. For discussion of cytologic presentation of malignant lymphoma, see Chapter 31.

TABLE 21-2 RESULTS OF CYTOLOGIC FOLLOW-UP ON PATIENTS WITH TREATED CANCER OF THE OROPHARYNX WITHOUT VISIBLE LESIONS AT THE SITE OF PRIOR SURGERY

THE LARYNX

METHODS OF INVESTIGATION

It is evident that cytologic examination of the larynx is possible only if an otorhinolaryngologist interested in this noninvasive

P.727

method of diagnosis is willing to obtain a cytologic sample during a **direct or indirect laryngoscopy**. Most papers describing the cytology of the larynx were written by interested clinicians, usually in association with a cytopathologist. A variety of methods were described to obtain the cell samples, ranging from a **simple cotton swab to sophisticated scrapers or brushes**. Carcinoma of the larynx may also be discovered in **samples of sputum** (see Chap. 20).

cancer cells and a large macrophage with phagocytosis of melanin pigment. *B.* Tissue biopsy of the same lesion, showing accumulation of melanin.

BENIGN LESIONS

Reaction to Intubation

The common practice of insertion of tubes into the larynx may lead to a necrosis and ulceration of the epithelium, followed by repair. It is not uncommon to have samples of the material aspirated for toilette purposes submitted for cytologic examination.

Sheets of small squamous cells with **marked nuclear abnormalities** are commonly observed in such patients (Fig. 21-10). Of particular interest is the presence of large nucleoli, a feature commonly seen in "repair." These cells may be mistaken for poorly differentiated squamous- or adenocarcinoma, unless the clinical history of intubation is available. As a general rule, **the diagnosis of cancer should not be made in samples obtained from intubated patients or patients on respirators.**

Another form of reaction to long-term intubation is **tracheitis sicca**, mimicking squamous cancer, described in Chapter 19.

Rhinoscleroma

A cytologic diagnosis of **rhinoscleroma of the larynx** was reported by Zaharopoulos and Wong (1984). **Large macrophages with phagocytized encapsulated bacilli (Mikulicz cells)** were illustrated. The bacterium causing the disease is the gram-negative *Klebsiella rhinoscleromatis*, which usually causes obstructive nasal lesions, responding to antibiotics.

TUMORS

Papillomatosis

Laryngeal papillomatosis was briefly mentioned in reference to papillomatosis of the bronchus (see Chap. 20). The interest in this disease has grown exponentially since its association with **human papillomavirus (HPV) type 11** was documented (Gissmann et al, 1982; Mounts et al, 1982; Mounts and Shah, 1984). Laryngeal papillomas are **squamous papillomas**, histologically very **similar to condylomata acuminata** (see Chaps. 11 and 14). As a rule, the lesions are multiple, may grow rapidly, and may cause obstruction of the larynx. It has been reported that the number of immunoactive intraepithelial cells (Langerhans' cells) is markedly reduced in these lesions (Chardonnet et al, 1986).

The disease occurs in two forms: a **juvenile form** affecting children, with the onset usually under the age of 5, and an uncommon **adult form** that usually manifests itself after the age of 20. It is postulated that in the juvenile form, HPV type 11 is **transmitted from the mother to the offspring during birth**. In fact, many of the mothers give a history of genital condylomata acuminata. Both forms are characterized by a chronic course and recurrences after treatment. Persistence of HPV in the laryngeal epithelium after removal of the lesions has been documented (Steinberg et al, 1983). A spread of the lesions into the trachea and the bronchi is common. Obstruction of the airway is an everexisting danger. **Malignant transformation of laryngeal papillomas into squamous carcinoma, although rare, does occur.** In a case reported by Byrne et al (1987), the presence of HPV type 11 in the primary tumor and in the

metastases was observed.

There has been no attempt known to this writer to use cytologic techniques for the diagnosis of primary or recurrent

P.728

laryngeal papillomatosis. However, the cytologic findings in the **bronchial manifestations are consistent with HPV infection** (see Chap. 20).

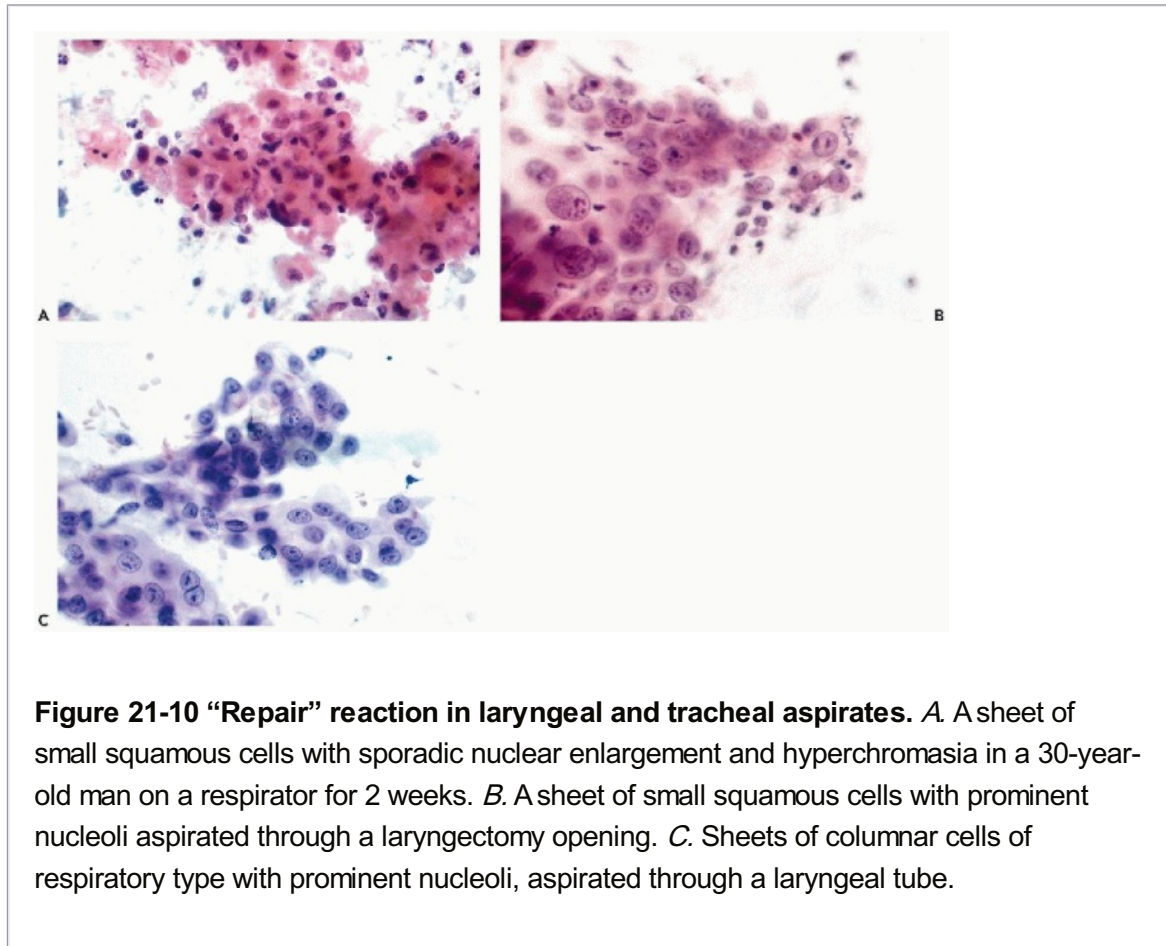

Figure 21-10 “Repair” reaction in laryngeal and tracheal aspirates. *A.* A sheet of small squamous cells with sporadic nuclear enlargement and hyperchromasia in a 30-year-old man on a respirator for 2 weeks. *B.* A sheet of small squamous cells with prominent nucleoli aspirated through a laryngectomy opening. *C.* Sheets of columnar cells of respiratory type with prominent nucleoli, aspirated through a laryngeal tube.

Carcinoma

The vast majority of the malignant tumors of the larynx are **squamous carcinomas**, many of which are keratin-producing. Brandsma et al (1986) reported the presence of **HPV type 16** in one such cancer. Invasive cancers of the larynx are nearly always symptomatic, with persisting hoarseness as the presenting symptom. The grading and staging of laryngeal carcinomas is similar to that of the oral cavity. A stage of **carcinoma in situ**, often classified as “**dysplasia**,” preceding invasive cancer, is well known.

Cytology

Although biopsy is the method of choice in the diagnosis of these tumors, Frable and Frable (1968), Beham et al (1997), and Malamou-Mitsi et al (2000) reported high levels of cytologic accuracy in smears obtained at the time of direct laryngoscopy, prior to biopsy. The cytologic findings are **identical to those described for similar cancers of the oral cavity**.

There is ample evidence that **invasive carcinoma of the larynx is preceded by carcinoma in situ**. The latter lesion may either be **keratinized, hence, white on inspection (leukoplakia)**, or **nonkeratinized, which produces an area of redness**. It must be stressed

that not all areas of leukoplakia harbor carcinoma. **Hyperkeratosis may also occur in the absence of cancer.**

In one of the early attempts at cytologic diagnosis of laryngeal lesions, a cotton swab smear of the larynx led to diagnosis of **squamous carcinoma in situ** in a man age 50 with mere redness of the vocal cords. **Dyskaryotic (dysplastic) squamous cells with abundant cytoplasm and enlarged, hyperchromatic nuclei were characteristic of this lesion** (Fig. 21-11).

Lundgren et al (1981) used a small wooden pin and a small brush to obtain cell samples from the larynx of 350 patients during direct laryngoscopies. The technical quality of the smears and the accuracy of the procedure were judged to be good. **Several cases of carcinoma in situ and “severe” and “moderate” dysplasia** were recorded. It is evident that the term **“dysplasia”** was used to describe a precancerous lesion because 46 of the 120 patients with this cytologic diagnosis proved to have invasive cancer, and 37 had carcinomas in situ. There were 26 lesions judged benign on biopsy, 25 of them with the diagnosis of “moderate dysplasia” and some of them possibly occult carcinomas, as documented by the authors in one case with adequate follow-up. There were also 33 malignant lesions missed by cytology for various reasons. The sensitivity of the procedure was estimated at 83% and the specificity at 84%. In a recent

P.729

publication based on a small number of patients, Malamou-Mitsi et al (2000) reported a specificity of 100% and sensitivity of more than 90%.

Figure 21-11 Carcinoma in situ of larynx. Primary diagnosis by smear. **A.** Swab smear of a slightly reddened larynx in a 54-year-old man. Note the excellent differentiation of abnormal cells resembling “dyskaryosis.” **B.** The lesion proved to be a carcinoma in situ as shown here.

A relatively large number of occult carcinomas of the larynx were discovered in **sputum** during the search for occult bronchogenic carcinomas (see Chap. 20). The cancer cells in sputum do not differ from those of a bronchogenic squamous carcinoma. It must be stressed that **identical cytologic presentation may also be observed in similar carcinomas of the oral cavity,**

the nasopharynx, and the trachea. These areas must be investigated if the sputum is positive and if there is no clinical evidence of oral or lung cancer.

There are very few benign cytologic abnormalities of the larynx that can mimic squamous carcinoma. The **small squamous cells found in sputum in cases of laryngitis, known as Pap cells**, are perhaps the only finding of note (see Chap. 19). Frable and Frable (1968) and Lundgren et al (1981) pointed out that **radiation changes**, similar to those observed in the uterine cervix or the lung, may occur in larynges that have been irradiated for invasive carcinoma (see Chaps. 18 and 19). The importance of careful follow-up of patients after laryngectomy for carcinoma has been stressed elsewhere (see Chap. 20).

Other malignant tumors of the larynx are uncommon. These include **carcinomas of minor salivary glands** (Spiro et al, 1973) and the rare **small-cell endocrine tumor** of the same origin (Koss et al, 1972). An exceedingly rare form of **squamous carcinoma of the larynx with a spindle cell component** (pseudosarcoma) has been reviewed by Goellner et al (1973). The prognosis of this tumor is surprisingly favorable, as is the case with similar tumors of the esophagus (see Chap. 24). The cytologic presentation of these rare tumors has not been described.

THE TRACHEA

REPAIR REACTION

As described above, an injury to the trachea during intubation or tracheostomy may result in florid squamous metaplasia or “repair” reaction. **Sheets of immature squamous cells** with monotonous, but somewhat enlarged, clear nuclei containing large nucleoli may be seen (see Fig. 21-10).

CARCINOMAS

Primary carcinomas of the trachea are uncommon. The symptomatology of tracheal carcinoma is the same as for bronchogenic carcinoma—cough and hemoptysis. Rarely, such lesions may cause asthmatic attacks (Baydur and Gottlieb, 1975).

Carcinomas of the trachea are primarily of two types: squamous carcinoma, which may be synchronous or metachronous with bronchogenic carcinoma and is often keratinizing; and **adenoid cystic carcinoma of minor salivary (mucous) glands**. The latter lesion is identical with adenoid cystic carcinoma of major salivary or bronchial glands and is described in the appropriate chapters.

Hajdu and Koss (1969) reported the cytologic findings in 14 patients with tracheal carcinoma, of which 10 were squamous and 4 were adenoid cystic. The **squamous cancer** was recognized either in **sputum** or in **tracheobronchial aspirates** in 9 of 10 patients. All 4 **adenoid cystic carcinomas** were recognized in **direct tracheal aspirates**.

The **cytologic presentation of squamous carcinoma** of the trachea was in every way similar to squamous carcinoma of the bronchus (see Chap. 20) or the larynx (Fig. 21-12). As is the case in other organs, the **adenoid cystic carcinoma was characterized by tightly packed clusters of small cancer cells** with scanty cytoplasm, often surrounding a **central core** of transparent hyaline material composed of layers of reduplicating basement membranes and forming the “cystic” component of the tumor (Fig. 21-13).

Figure 21-12 Epidermoid carcinoma of trachea. *A.* Cluster of cells of epidermoid carcinoma in sputum. Note the enlarged, hyperchromatic nuclei. *B.* Histologic appearance of tumor. (From Hajdu SI, Koss LG. Cytology of carcinoma of the trachea. *Acta Cytol* 13:256-259, 1969.)

Figure 21-13 Adenoid cystic carcinoma of the trachea. *A,B.* Tracheobronchial aspirate. Typical tight clusters of uniform small cancer cells, one with central space containing hyaline material (*arrow*). *C.* Similar central deposits of material may be observed in the histologic section (*arrowheads*). Tracheal cartilage is seen in the bottom of the last photograph. (From Hajdu SI, Koss LG. Cytology of carcinoma of the trachea. *Acta Cytol* 13:256-259, 1969.)

P.731

THE NASOPHARYNX

METHODS OF SAMPLING AND INDICATIONS

Cytologic examination of the nasopharynx requires direct scraping, which is best performed under visual control with a fiberoptic instrument.

The diagnostic sampling has several applications including to confirm an allergic disorder, such as asthma, or the detection of nasopharyngeal neoplasms, as narrated below.

NORMAL SMEARS

Scrape smears from nasopharyngeal epithelium contain **squamous cells, ciliated respiratory type cells, and goblet cells**; hence, their makeup is similar to that of bronchial smears (Fig. 21-14).

Figure 21-14 Nasopharynx: inflammation. Note a mixture of ciliated columnar cells against a background of polymorphonuclear leukocytes.

INFLAMMATORY DISORDERS AND BENIGN TUMORS

Cytology of the nasopharynx has been extensively studied in patients with **common colds or upper respiratory tract viral infections**. In smears, there is **partial or total necrosis of the exfoliated respiratory epithelium and changes similar to ciliocytophthoria**, described in Chapter 19. In **asthma**, a marked increase of **eosinophilic leukocytes** may be noted.

In an aspirate of the nasopharynx, we observed **markedly atypical degenerated macrophages** with markedly enlarged and hyperchromatic, yet homogeneous single or multiple nuclei, shown in Figure 21-15. The cells were mistaken for cancer cells but long-term follow-up of the patient failed to reveal a primary or metastatic tumor.

Fortin and Meisels (1974) reported a case of **rhinosporidiosis** of the nasal cavity, a disease caused by a fungus *Rhinosporidium seeberi*. The disorder causes polyp-like lesions. Large

numbers of ovoid spores are characteristic of this infection. An incidental finding of **amyloidosis** in a smear from a nasopharyngeal carcinoma was reported by Chan et al (1988).

A number of disorders on the border of inflammation and neoplasia may affect the nasopharynx. Among them are **Wegener's granulomatosis (lethal midline granuloma)**, which may culminate in a malignant lymphoma. There is limited information on the cytologic presentation of these disorders. The presence of **smooth muscle cells** in sputum in a case of Wegener's granulomatosis with ulceration of bronchial lining was reported by Takeda and Burechailo (1969; see Chap. 20).

Jones et al (2000) described a rare disorder known as **pyogenic granuloma** or **pregnancy tumor** of the nasal cavity of pregnant women. The disorder, also known as **hemangiomatous granuloma**, is a red, rapidly growing tumor of unknown etiology (reviews in Smulian et al, 1994; Sills et al, 1996). The tumor may be mistaken for other neoplasms with a rich capillary component, such as malignant hemangioma or Kaposi's sarcoma. There are no reports on cytologic presentation of pyogenic granuloma but the technique should prove useful in the differential diagnosis.

MALIGNANT TUMORS

Nasopharyngeal Carcinoma

For unknown reasons, the incidence of carcinoma of the nasopharynx is very high among **ethnic Chinese** (Chien et al, 2001). In Norway, nasopharyngeal epidermoid carcinoma was observed in **nickel workers** (Torjussen et al, 1979) in whom various stages of precancerous abnormalities ranging from loss of cilia to squamous metaplasia, to carcinoma in situ, could be observed.

The association of nasopharyngeal carcinomas with **Epstein-Barr (EB) virus** is well documented (summaries in Purtilo and Sakamoto, 1981; Cohen, 2000; Chien et al, 2001). It is not known what role, if any, the virus plays in

P.732

the genesis of the tumors. However, **the presence of the EB virus, documented by molecular techniques in aspirated cell samples from metastatic tumors in neck lymph nodes, supports the presumption of origin from a primary nasopharyngeal carcinoma** (Feinmesser et al, 1992). The presence in serum of serologic markers for EB virus was predictive of nasopharyngeal carcinoma (Chien et al, 2001).

Figure 21-15 A typical benign macrophages in nasopharyngeal aspirate. A and B

show cells with markedly enlarged, hyperchromatic nuclei, mistaken for cancer cells. In *B*, the abnormal nuclei are multiple. In *B*, the huge size of the abnormal cells may be compared with that of three normal macrophages in the same field. A careful work-up of the patient and many years of follow-up failed to reveal any evidence of cancer. Hence, it may be assumed that the cells are degenerated, markedly atypical, but benign macrophages.

Histology

Muir and Shanmugaratnam (1967) studied 994 cases of carcinoma of the nasopharynx and subdivided the tumors into **three main groups of tumors**, namely, **squamous carcinoma, nonkeratinizing carcinoma, and undifferentiated carcinoma**, the latter including **nonkeratinizing carcinomas** and the tumors known as **lymphoepitheliomas** (also known as Schmincke's or Regaud's tumors). Only 1% of the tumors were found to be of other types and included **mucus-producing carcinomas** of colonic type and **olfactory neuroblastomas (esthesioneuroblastomas)**, discussed below. The significance of this tumor classification in reference to response to radiation treatment and survival showed that undifferentiated carcinoma offered the best prognosis (Shanmugaratham et al, 1979).

The **lymphoepitheliomas are characteristically composed of large, undifferentiated tumor cells with pale nuclei and large nucleoli, embedded in a stroma rich in lymphocytes**. Primary lymphoepitheliomas may be asymptomatic but tend to **metastasize early to the lymph nodes of the neck and the metastasis may be the first manifestation of the tumor, a fact also emphasized by Dr. MY Ali, at the University of Singapore**.

Pathmanathan et al (1995) reported that clonal proliferation of cells infected with EB virus, obtained from the nasopharynx, was diagnostic of **precancerous lesions** such as **dysplasia and carcinoma in situ**. The authors speculated that the presence of **EB virus transforming gene LMP-1** was essential for neoplastic proliferation to take place.

Cytology

Ali (1965) adopted cytologic techniques to the diagnosis of nasopharyngeal carcinoma, using swab smears, obtained with cotton-tipped applicators. **Squamous or epidermoid carcinomas of the nasopharynx do not significantly differ from squamous cancers in other locations. Undifferentiated carcinomas** (including lymphoepitheliomas) were characterized by **large cancer cells with scanty cytoplasm and prominent irregular nuclei, often with large multiple nucleoli** (Fig. 21-16). The **lymphoepitheliomas** also contained a **population of lymphocytes** in the smear. Because these tumors often metastasize to lymph nodes of the neck (as noted, sometimes as the first manifestation of disease), **aspiration biopsy of the lymph node metastases is of significant diagnostic value** (Fig. 21-17). In most instances, the tumors cannot be specifically identified, except that they are epithelial in nature. As has been discussed above, the presence of EB virus in the material aspirated from lymph nodes supports the nasopharyngeal origin of the tumor (Feinmesser et al, 1992).

Results

Ali's results are summarized in Table 21-4. The results pertain largely to fully developed malignant tumors from symptomatic patients and are generally less satisfactory than results from other sites within the head and neck area. The difficulty of obtaining adequate samples from ulcerated and bulky tumors may account for these results. Ali's results compare favorably

with those obtained by others and quoted by Ali from sources largely inaccessible to this author. With the exception of two small studies in the United States (Morrison et al, 1949; Hopp, 1958), the accuracy is below 50% of all cancers investigated. In view of the very high incidence of cancers of the nasopharynx among the Chinese, a cancer detection project, having for its purpose developing more effective cytology sampling with improved diagnosis of these lesions in preclinical stages, would seem

P.733

worthwhile. The observation of Pathmanathan et al (1995), cited above, may conceivably serve this purpose.

Figure 21-16 Cytologic aspects of cotton-swab smears of three undifferentiated nasopharyngeal carcinomas. Scantiness of cytoplasm, anisonucleosis, and very large nucleoli are readily observed. In *A*, a single lymphocyte is present. In *C*, a few lymphocytes are intermingled with the much larger cancer cell nuclei. *D*. Histologic section of an undifferentiated nasopharyngeal carcinoma. Note the lymphoid component. (Courtesy of Dr. M.Y. Ali, Singapore.)

OTHER TUMORS

The rare **adenocarcinomas of colonic type** were not studied cytologically. **Olfactory neuroblastoma or esthesioneuroblastoma** is a rare tumor of the nasopharynx of adults, derived from olfactory neural elements. The tumor structurally mimics a neuroblastoma, although it has a much better prognosis. **Rosette formation by small tumor cells**, with an accumulation of **neurofibrils** in the center is characteristic of this tumor. A case of this rare tumor diagnosed cytologically from a scrape smear of the nasal vault was reported by Ferris et al (1988). Another such case, diagnosed by thinneedle aspiration of the tumor, was reported by Jelen et al (1988). The cytologic features of neuroblastoma in aspiration biopsy are discussed in Chapter 40.

Other rare tumors of the nasopharynx such as **chordoma**, **craniopharyngioma**, and **plasmocytoma** will be briefly described and illustrated in appropriate chapters (also see article by Scher et al, 1988).

PARANASAL SINUSES

Malignant tumors of the paranasal sinuses comprise **squamous or epidermoid carcinomas**, **adenocarcinomas**, mainly of minor salivary (mucous) gland origin, the so-called **schneiderian carcinomas**, resembling urothelial carcinomas, and an occasional rarity such as a primary **melanoma or sarcoma**. In debatable clinical situations, washings from the paranasal sinuses may be submitted for cytologic evaluation. In most instances, the cytologic material shows evidence of acute or chronic inflammation, reflecting sinusitis. Occasionally, however, evidence of cancer may be observed, thereby clarifying the clinical situation. The cytologic presentation of these malignant tumors is identical with tumors of similar histological pattern arising in the oral cavity, larynx, trachea, and nasopharynx.

P.734

Figure 21-17 Metastatic nasopharyngeal carcinoma to lymph nodes as the first manifestation of disease. *A,B.* Scattered, small malignant cells, singly and in clusters, and lymphocytes in an aspirated sample from the enlarged neck nodes in a 23-year-old Chinese patient. *C,D.* Biopsy of the polypoid tumor of the nasopharynx. *C* shows the

surface of the lesion, lined by benign epithelium. *D* shows the tumor composed of sheets of large epithelial cells surrounded by lymphocytes (lymphoepithelioma).

TABLE 21-4 THE ACCURACY OF DETECTION OF MALIGNANT CELLS IN NASOPHARYNGEAL SMEARS

	Total Number Examined	Histologically Confirmed Malignancy			Histologically Negative for Cancer		Overall Accuracy

The Lower Urinary Tract in the Absence of Cancer

URINARY TRACT CYTOLOGY: ITS ACCOMPLISHMENTS AND FAILURES IN HISTORICAL PERSPECTIVE

Examination of urine belongs among the oldest medical procedures in the history of mankind. Ancient Egyptians were aware of the importance of bloody urine in the diagnosis of bladder disorders that were later identified as cancer caused by the parasite *Schistosoma haematobium*. As noted in an important historical contribution by Badr (1981), the papyrus of Kahun, dated 1900 years B.C., contains a hieroglyphic describing hematuria (Fig. 22-1). The gross inspection of urine (often collected in special containers) or "uroscopy" was an important diagnostic procedure for many centuries. Fisman (1993) presented an amusing account of the role played by uroscopy in 17th century England and pointed out that this practice persisted until the early years of the 20th century. In 1856, Wilhelm Duschan Lambl, a

P.739

Czech physician, published a remarkable paper on the use of the microscope for the examination of the urinary sediment at the bedside. Lambl described and illustrated a number of bladder conditions, including cancer (Fig. 22-2). This was the beginning of contemporary cytology of the urinary sediment. The reader is referred to other sources for a detailed description of these early events (Koss, 1995).

Figure 22-1 Hematuria, as recorded in the papyrus of Kahun (1900 B.C.), with reference to schistosomiasis. (From Badr M. Schistosomiasis in ancient Egypt. /n El-Bolkainy M, Chu EW (eds). Detection of Bladder Cancer Associated with Schistosomiasis. Cairo, Egypt, The National Cancer Institute, 1981.)

Nearly 150 years after the publication of Lambl's contribution on the cytology of the urinary

sediment, the benefits and limitations of this method of diagnosis are still poorly understood by urologists and pathologists. It would be a safe bet that the opinions of individual urologists may vary from total indifference to the method as worthless in clinical practice, to the rare enthusiastic endorsement, with the majority expressing a moderate degree of interest in a method of occasional value.

The problem with cytology of the urinary tract is the lack of **basic understanding of the accomplishments and limitations of the method** and of the pathologic processes accounting for it. As will be set forth in this and the next chapter, it is **unrealistic to expect that the cytologic method will serve to recognize the presence or recurrence of low-grade papillary tumors**. It is equally **unrealistic** to expect that cytology of urine, or of the various ancillary sampling procedures, will help in **differentiating low-grade papillary tumors from other space-occupying lesions of the renal pelvis or ureter**. This accounts for the introduction of numerous noncytologic methods of diagnosis by commercial companies, discussed in the next chapter.

On the other hand, cytologic techniques are highly effective in detection and diagnosis of **high-grade malignant tumors**, particularly **flat carcinomas in situ**, which are the principal precursor lesions of invasive urothelial cancer. Cytology of urine is also valuable in the recognition of various **viral infections**, particularly **human polyomavirus**, and the effects of **various therapeutic procedures**. In our judgment, cytology of the urinary tract is **one of the most important diagnostic methods in urologic oncology**, provided:

- It is used properly by the urologist under well-defined circumstances and for well-defined reasons.
- It is performed by a laboratory competent in processing and interpretation of such specimens.
- The urologist and the pathologist understand the limitations of the method and are familiar with sources of error.

Figure 22-2 Figures from Lambl's 1856 paper. Figure 11 illustrates various cells and crystals observed in the urinary sediment. Figure 13 shows a “Papillary pseudoplasma from the urethra of a girl”—undoubtedly a condyloma acuminatum.

Application of Cytology in Forensic Sciences

An unusual application of cytology is the **identification of female cells in postcoital swab smears of the penis**. Fluorescence in situ hybridization techniques were used to record female cells with two X chromosome signals (Collins et al, 2000). The technique may be helpful in proving sexual contact in cases of presumed rape.

ANATOMY

The urinary tract is composed of the **kidneys, ureters, urinary bladder, and urethra**. The position of these organs in the abdominal cavity and the methods of cytologic sampling are shown in Figure 22-3.

The **two kidneys are fist-sized, encapsulated organs** located laterally in the retroperitoneal space. The principal function of the kidney is to **filter** blood and eliminate harmful products of metabolism and other impurities that are excreted in **urine**. The bulk of the kidney is constituted by the filtering apparatus or **nephrons**, each composed of the principal filtering device, or the **glomerulus**, connected to a series of **tubules**. The filtrate generated by the glomeruli

P.740

undergoes many modifications in the tubulus until the final product of the filtration process, or the **urine**, is excreted into the **renal pelvis**, whence it travels through the **ureters** to the **bladder**.

Figure 22-3 Diagram of the principal organs of the urinary tract and the methods of

investigation by either exfoliative or aspiration cytology. (Diagram by Dr. Diane Hamele-Bena, College of Physicians and Surgeons of Columbia University, New York, NY.)

The kidney is essential to the maintenance of osmotic equilibrium in the blood. It also contributes to the regulation of blood pressure and has several other ancillary functions. It is beyond the scope of this book to provide details on the complex structure and function of the kidneys and interested readers are referred to specialized sources for further information.

The **ureters** are firm cylindrical structures, about 20 to 25 cm in length and about 0.5 cm in diameter. In their course toward the bladder, the ureters cross the pelvic brim and enter the bony pelvis, and thence the **urinary bladder**. In the **female**, the **ureters pass near the lowest segment of the uterus** to reach the bladder. This relationship is important in patients with **invasive cancer of the uterine cervix** that can surround and obstruct the ureters.

The **bladder** is a balloon-shaped organ composed from inside out of an **epithelium**, a connective tissue layer known as **lamina propria**, and an elastic **muscular wall (muscularis propria)**. These component tissues work in unison to allow expansion of bladder volume while accumulating urine and collapse with voiding. Under pathologic circumstances, the bladder is capable of accommodating up to several liters of urine without rupture.

Lamina propria is a thin layer of connective tissue supporting the urothelium. It is rich in vessels and in most individuals, but not all, contains an **interrupted thin layer of smooth muscle cells (muscularis mucosae)**. The **nests of Brunner and the cysts of cystitis cystica** are located within the lamina propria. **Muscularis propria, or the principal muscle of the bladder**, is composed of two thick concentric layers of smooth muscle, in continuity with the **muscular wall of the ureters**.

The **embryologic derivation** of the bladder is in part from the **cloaca**, or the **terminal portion of the embryonal intestinal tract**. A vestigial organ, the **urachus**, a remnant of the embryonal omphaloenteric duct, connects the bladder dome with the umbilicus. Other parts of the bladder are derived from the **genital tubercle**. This dual embryonal origin accounts for the **variety of epithelial types** that may occur in the bladder (see below). The basal portion of the urinary bladder contains the **trigone**, a triangular area with the apex directed forward to the urethra. The two **ureters enter the bladder** at the posterior angles of the trigone. The urine passes from the bladder into the **urethra**, which begins at the apex of the trigone. The important anatomic relationships of the trigone differ between females and males. In the **female**, the trigone **overlies the vesicovaginal septum and the vagina**, whereas in the **male**, the immediately underlying organs are the **prostate and seminal vesicles**. It is evident that cancers of these various organs may extend to the trigone and vice-versa.

The **female urethra** has only a very short course and opens into the upper portion of the **vaginal vestibule**, somewhat behind and below the clitoris (see Chap. 8). In the **male**, the urethra runs **across and through the prostate** and enters the **penis**. The anatomy of the prostate is discussed in Chapter 33.

THE UROTHELIUM

Histology

Urine is a toxic substance and, hence, the **renal pelves, ureters, bladder, and urethra** must be capable of preventing the seepage of urine into the capillary bed in the wall of

these organs or, in other words, **protecting the urine-blood barrier**. This protective function is, at least in

P.741

part, vested in the **highly specialized type of epithelium** lining these organs. Because of its **unique structure and ultrastructure**, this epithelium should be referred to as the **urothelium**, but is often called by the **improper traditional term—transitional epithelium**. The urothelium is **uniquely flexible** and **adapts to the changing volume of urine in the bladder, without breaching the urine-blood barrier**.

In tissue sections, **the normal urothelium** is composed on **the average of seven layers of cells**, although **the number of cell layers may appear greater in contracted bladders and smaller in dilated bladders**. The **superficial cells of the urothelium, also known as the umbrella cells, are very large and are often multinucleated**. The term **umbrella cells** indicates that each superficial cell covers several smaller cells of the underlying deeper layer in an umbrellalike fashion. In **histologic sections of the bladder**, the umbrella cells vary in shape, according to the state of dilatation of the bladder. **In the dilated bladder, they appear flat; in the contracted bladder, they are more rounded or cuboidal** (Fig. 22-4C,D). In the renal pelvis, the ureters, and the urethra, the umbrella cells are usually cuboidal in configuration. The structure of umbrella cells is much better seen in cytologic material than in tissue sections (see below). The **deeper cell layers** are made up of cuboidal cells with a single nucleus. The schematic representation of the dilated and contracted mammalian urothelium is shown in Figure 22-4A,B. Cordon-Cardo et al (1984) and Fradet et al (1987) documented immunologic differences between deeper and superficial cells of the urothelium by means of various monoclonal antibodies. It should be added that Petry and Amon (1966) believed that cells in all layers of the urothelium were attached to basement membrane by means of cytoplasmic extensions. We were unable to confirm this observation.

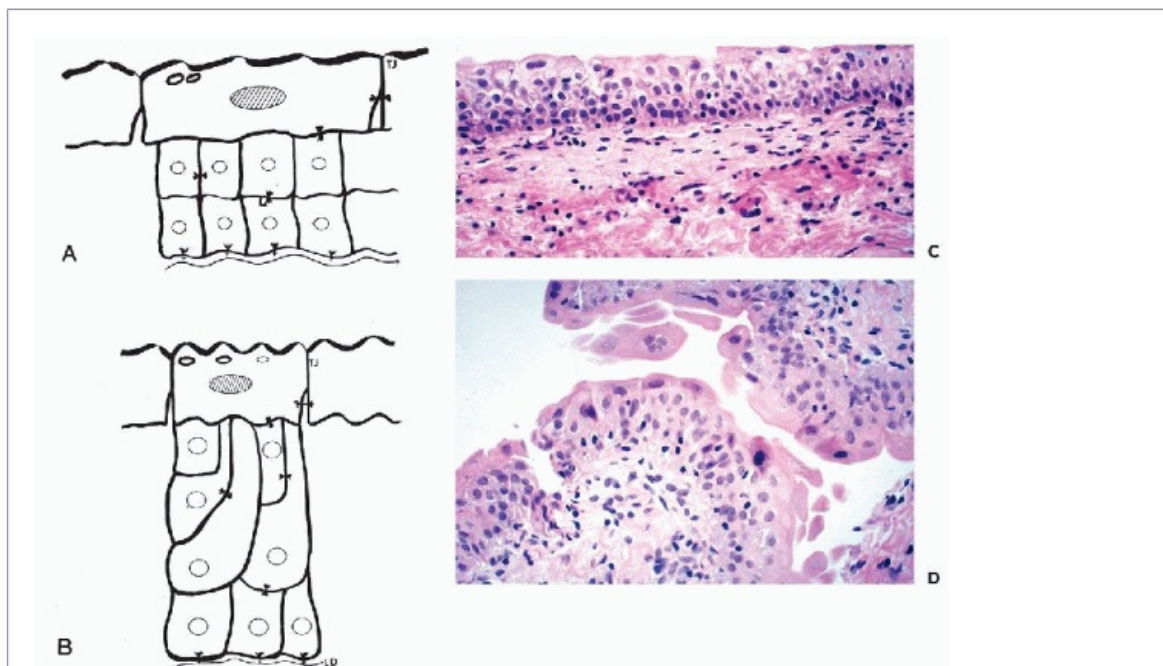

Figure 22-4 Diagrammatic representation of a dilated (A) and contracted (B) bladder urothelium to show the changes in cell configuration and the mechanism of cell movement. The superficial cells (umbrella cells) are shown lined by thick plaques of the asymmetric unit membrane, with intercalated segments of thin, symmetric membrane. The

structure of the membrane can be compared with medieval armor in which flexible links between metal plates provided mobility for the bearer. Near the surface, the umbrella cells are linked by tight junctions (TJ). Abundant desmosomes bind the epithelial cells. Hemidesmosomes bind the epithelium to the lamina densa (LD). Note the difference in the configuration of the superficial cells in the dilated and contracted bladder. *C.* Histologic section of a dilated bladder, corresponding to *A.* *D.* Histologic section of a contracted bladder, corresponding to *B.* Note differences in the configuration of umbrella cells. (*A,B:* Modified from Koss LG. Some ultrastructural aspects of experimental and human carcinoma of the bladder. *Cancer Res* 37:2824-2835, 1977.)

Ultrastructural observations disclosed that the umbrella cells in all mammals, including humans, are lined on their surface (facing the bladder lumen) by a **unique**

P.742

membrane known as the asymmetric unit membrane (AUM) (Hicks, 1966; Koss, 1969, 1977). The membrane has **two components—rigid, thick plaques and intervening segments of thin plasma membrane or hinges** (Fig. 22-5). The plaques, measuring about 13 nm in thickness, are composed of **three layers**; the two **outer layers are electron opaque and of unequal thickness**, the central layer is electron lucent. The term **asymmetric unit membrane** is descriptive of the difference in thickness of the electron-opaque components. It is assumed that the plaques may play a role in the urine-blood barrier, whereas the **intervening segments of plasma membrane act like hinges, providing flexibility to the plaques, thereby ensuring that the umbrella cells can adapt to changing urinary volume requirements** (Fig. 22-4C,D). There is some experimental evidence that the destruction of the superficial cells increases the permeability of the bladder to lithium ions (Hicks, 1966). Still, the urine-blood barrier remains in place, even in the absence of umbrella cells or of the asymmetric plaques, as is common in older persons (Jacob et al, 1978). Hu et al (2000) suggested that this function is vested in one of the membrane proteins, uroplakins (see below). Ablation of the uroplakin III gene in mice resulted in formation of smaller epithelial plaques and urothelial leakage. Still, it is likely that the urine-blood barrier function is also vested in other components of the bladder wall, such as the basement lamina and the muscle. For discussion of uroplakins, see below.

The AUM is produced in the Golgi complex of the superficial cells and travels to the surface packaged into oblong vesicles (Fig. 22-5), as was documented many years ago (Hicks, 1966; Koss, 1969, 1977). The **chemical structure** of the AUM has been unraveled. Its protein components, known as **uroplakins Ia, Ib, II, III**, have been analyzed and sequenced and their role as marker molecules will be discussed in the next chapter (Yu et al, 1990; Wu et al, 1990, 1994; 1996). The particles of the uroplakins form well-ordered hexagonal lattices (Walz et al, 1995). Liang et al (1999) studied the **chemical make-up of the “hinges,”** located between the plaques in bovine urothelium. They reported that these segments of the urothelial surface membrane have a specialized chemical make-up, differing from the plaques.

Figure 22-5 Electron micrograph of a superficial cell of moderately dilated rat bladder. Note the characteristic oblong vesicle (V) lined by a rigid, asymmetric unit membrane, morphologically identical with segments of the cell membrane (C). L, lumen of bladder. Fine tonofilaments (T) are evident as well as a few round vesicles and mitochondria. ($\times 20,400$.)

The **deeper epithelial cells** are of approximately cuboidal shape and are attached to each other by numerous **desmosomes**. These cells have no specific ultrastructural features.

Of signal interest is a series of studies suggesting that the urothelium may have highly specialized **active functions**, such as regulating protein secretions in urine (Deng et al, 2001) and secretion of growth hormone (Kerr et al, 1998).

It is of note that human urothelial cells can be successfully cultured from the sediment of voided urine (Herz et al, 1979). The AUM may persist in several generations of these cells (Shokri-Tabibzadeh et al, 1982).

Epithelial Variants in the Lower Urinary Tract

Because of its diverse embryonal origin, the lower urinary tract may be partially lined by epithelia other than the urothelium. These are:

- Squamous epithelium of vaginal type
- Intestinal type glandular epithelium
- Brunn's nests and cystitis cystica

The location and distribution of these epithelial variants was documented by mapping studies of normal bladders (Morse, 1928; Wiener et al, 1979; Ito, 1981). The frequency of these epithelial variants is summarized in Table 22-1.

Squamous Epithelium of the Vaginal Type

The **trigone of the bladder** in approximately 50% of normal adult women and in a small

proportion of men contains areas of **nonkeratinizing squamous epithelium of the vaginal type** (Fig. 22-6A). In cystoscopy, this area may appear as a gray membrane. Although this is merely an anatomic variant of bladder epithelium and evidence of inflammation

P.743

is usually absent, this condition has been recorded clinically as “**urethrotrigonitis**,” “**epidermidization**,” or “**membranous trigonitis**.” In women, **this epithelium appears to be under hormonal control** and is the most likely source of squamous cells in **urocytograms**, described in Chapter 9.

TABLE 22-1 FREQUENCY OF EPITHELIAL VARIANTS IN 100 CONSECUTIVE NORMAL BLADDERS (61 MALE, 39 FEMALE; 8 CHILDREN AND 92 ADULTS)

Total bladders with one or more lesions: 93

	Male	Female
Brunn's nests	53	36
Cystitis cystica	32	28
Vaginal metaplasia	3	19
None	6*	1*

* Two newborns: 1 male, 1 female. 5 males: 4 adults, 1, age 13. From Weiner et al, 1979.

Figure 22-6 Variants of urothelium. A. Squamous epithelium of the vaginal type from the

trigone of an adult woman. *B.* Glandular epithelium of intestinal type, adjacent to plugs of squamous epithelium from an exstrophic bladder in a 7-year-old child. *C.* Nests of Brunns. *D.* Cystitis cystica.

Intestinal-Type Epithelium

Because the embryonal intestinal tract (the cloaca) participates in the formation of the lower urinary tract, areas of **mucus-producing intestinal-type epithelium with goblet cells may occur in the bladder, the ureters, and even the renal pelves**. In most patients, these areas are small, but **occasionally the bladder (sometimes also the ureters and the renal pelves) may be fully or partially lined by this type of the epithelium** (Fig. 22-6B). This is particularly evident in **exstrophy**, a congenital abnormality in which at birth, the bladder is located outside of the abdominal wall, but may also occur in anatomically normal organs (Koss, 1975). The intestinal type epithelium may contain **endocrine Paneth cells**. When the surface lined by intestinal epithelium is large, it presents a **high risk for adenocarcinoma**.

Brunn's Nests and Cystitis Cystica

The urothelium of the bladder may form small, usually round **buds, known as** the nests of von Brunn (**Brunn's nests**) that extend into the lamina propria, occasionally to the level of the muscularis. Brunn's nests occur in approximately 80% of normal bladders. Occasionally, a florid proliferation of Brunn's nests may occur within the lamina propria (Volmar et al, 2003). Within the **center of Brunn's nests, there is often formation of cysts, which may be lined by mucus-producing columnar epithelium** (Fig. 22-6C). The cysts may become quite large and distended with mucus, giving rise to so-called **cystitis cystica or glandularis** (Fig. 22-6D). Gland-like cystic structures may also arise directly from the urothelium without going through the stage of Brunn's nests. Some of these structures **may express prostate-specific antigen** (Nowels et al, 1988). It is traditional to consider Brunn's nests and cystitis cystica as an expression of abnormal urothelial proliferation, either caused by an inflammatory process or as an expression of a neoplastic potential. This most **emphatically is not true**. The mapping studies of normal urinary bladders disclosed that such findings are common in normal bladders and must be considered as mere anatomic variants of the urothelium (Morse, 1928; Wiener et al, 1979; Ito, 1981).

Nephrogenic adenoma or adenosis is an uncommon benign lesion of the urinary bladder, composed of cystic spaces of various sizes lined by cuboidal epithelial cells (Koss, 1985). The lesion may contain elements of renal tubules. The lesion is of no diagnostic significance in urinary tract cytology, unless it becomes a site of an adenocarcinoma.

P.744

CYTOLOGY OF THE LOWER URINARY TRACT

As indicated in the anatomic diagram (see Fig. 22-3), there are two principal methods of cytologic sampling of the urinary tract: **exfoliative cytology** based on voided urine, washings or brushings of the epithelial surfaces, and **needle aspiration techniques** of solid organs, the kidneys, adrenals, retroperitoneum, and prostate. In this chapter, only the exfoliative cytology of the epithelial surfaces of the lower urinary tract is described. Aspiration biopsy of the solid organs is described in Chapters 33 and 40.

Methods of Specimen Collection

The principal methods of specimen collections are:

- Voided urine
- Catheterized urine
- Direct sampling techniques
 - Bladder washings or barbotage
 - Cell collection by retrograde catheterization of ureters
 - Direct brushings

The selection of the method of specimen collection and processing depends on clinical circumstances and the goal of the examination. The advantages and disadvantages of the various methods are summarized in Table 22-2.

Voided Urine

This is by far the easiest and least expensive method of cytologic investigation of the urinary tract. The technique is valuable **as a preliminary assessment of a broad spectrum of abnormalities of the urethra, bladder, ureters and renal pelves** and, under special circumstances, of the kidney and prostate.

Urine is an acellular liquid product of renal excretory function. As the liquid passes through the renal tubules, renal pelvis, ureter, bladder, and urethra, it picks up desquamating cells derived from the epithelia of these organs. Inflammatory cells, erythrocytes, and macrophages are frequently seen. Voided urine normally has an acid pH and a high content of urea and other organic components; therefore, it is not isotonic. Consequently, **the urine is not a hospitable medium for desquamated cells, which are often poorly preserved and sometimes difficult to assess on microscopic examination.**

Collection

Morning urine specimens have the advantage of highest cellularity, but also the disadvantage of marked cell degeneration. **A specimen from the morning's second voiding is usually best. Three samples obtained on 3 consecutive days are diagnostically optimal** (Koss et al, 1985). Naib (1976) recommended hydration of patients to increase the yield of desquamated cells (1 glass of water every 30 minutes during a 3-hour period).

Processing

Unless the urine is processed without delay, the addition of a **fixative** is recommended. In our hands, the **best fixative is 2% polyethylene glycol (Carbowax) solution in 50% to 70% ethanol** (Bales, 1981). To achieve best results, the patient should be provided with a 250 to 300 ml wide-mouth glass or plastic container one-third filled with fixative. This makes it convenient for **home collection** of samples.

The urinary sediment can be processed in a variety of ways. The specimen can be centrifuged for 10 minutes at moderate speed and a **direct smear of the sediment** made on adhesive-coated slides. The urine **can be filtered** using one of the commercially available filtering devices, either for **direct viewing** of cells on the surface of the filter, or after transferring the filtered cells to a glass slide by imprinting them (**reverse filtration**). Alternatively, the cellular

sediment can be placed on an adhesive-coated slide by use of a **cytocentrifuge**, preferably using the **method developed by Bales** (1981) in our laboratory. Several commercial methods of preparation of the urinary sediment have been developed within recent years. Urine sediment preparation by ThinPrep has been reported by Luthra et al (1999) as giving satisfactory results. Both ThinPrep and SurePath gave satisfactory results to Wright and Halford (2001). Still, these methods **may modify the appearance of urothelial cells, particularly their nuclei**. For further details on sample processing, see Chapter 44. The use of **phase microscopy** (de Voogt et al, 1975) and of **supravital stains** (Sternheimer, 1975) in the assessment of urine cytology has been suggested. Neither method received wide acceptance.

Catheterized Urine

The specimens are collected via a catheter and processed as described above for voided urine.

Direct Sampling Techniques

Bladder Washings or Barbotage

This procedure may be used to obtain **cellular specimens of well-preserved epithelium from patients at high risk for development of new or recurrent bladder tumors**. It is the specimen of choice for **DNA ploidy analysis** of the urinary epithelium, discussed in Chapters 23 and 47. The bladder should first be emptied by catheter. Bladder barbotage is then best performed **during or prior to cystoscopy** by instilling and recovering 3 to 4 times 50 to 100 ml of normal saline or Ringer's solution. The procedure can also be performed through a **catheter** but it is uncomfortable, particularly for male patients, and the results are less satisfactory.

Retrograde Catheterization of Ureters or Renal Pelves

This procedure is used **to establish the nature of a space-occupying lesion** of ureter or renal pelvis, observed by radiologic techniques. The most common application of the procedure is in the **differential diagnosis between a stone, a blood clot, or a tumor**. Other rare, space-occupying lesions of the **renal pelves** are **inflammatory masses, angiomas,**

P.745

and congenital aberrations of the vascular bed. In the **ureter**, there may be lesions caused by a **tumor, a stricture, or extraneous pressure**.

TABLE 22-2 PRINCIPAL ADVANTAGES AND DISADVANTAGES OF VARIOUS CYTOLOGIC METHODS OF INVESTIGATION OF THE LOWER URINARY TRACT

Method	Advantages	Disadvantages	Remarks
Voided urine	Efficient method for diagnosis of high grade tumors (including carcinoma in situ) of bladder, ureters, and renal pelves. Unique method for the diagnosis of human polyomavirus infection . The	The findings are not consistent, and three or more specimens should be	All methods fail in consistent identification of low-grade tumors. For exceptions, see text.

	method is of value in monitoring patients with locally treated tumors and patients with renal transplants. Examination can be repeated without harming the patient.	examined for optimal results. Sources of error must be known.	
Catheterized urine	Same as voided urine. Less contamination with cells of female genital tract.	Same as voided urine.	
Bladder washings	Same as voided urine, but results confined to bladder. The diagnosis of high-grade tumors is sometimes easier. Ideal medium for DNA measurements.	The method is poorly tolerated by ambulatory patients, particularly males. Optimal results may require cystoscopy.	Fragments of low-grade tumors may sometimes be recognized, but beware of errors. See text. Useful to confirm occult carcinoma or CIS in bladder when cancer cells are found in voided urine.
Retrograde brushing	Occasionally useful in the identification and localization of high grade tumors of ureters and renal pelves.	A major source of diagnostic errors (see below and Chap. 23). The value of the procedure in the differential diagnosis of space-occupying lesions of ureters or renal pelves is very low.	
Drip urine collected from ureters	Efficient method of localization of high grade tumors of ureters and renal pelves.	A time-consuming procedure.	Separate catheters must be used for

			each side to avoid contamination.
Ileal bladder urine	Efficient in the diagnosis of metachronous high grade tumors of ureters and renal pelves after cystectomy for bladder cancer. Occasional primary lesions of ileal conduit may be observed.	Same as voided urine. Knowledge of cytologic presentation is essential.	A mandatory follow-up procedure after cystectomy for bladder cancer.
Modified from: Koss LG. Diagnostic Cytology of Urinary Tract. Philadelphia, Lippincott-Raven, 1996.			

Another important application of this technique **is the localization of an occult malignant tumor diagnosed in voided urine sediment but not found in the bladder**. The purpose is to determine whether the tumor can be **localized in the left or right** kidney or ureter. For urine collection, **separate catheters must be used for each side** to avoid cross-contamination. The best results are obtained by **inserting the catheter to a depth of 3 to 4 cm into the ureters and by placing the other tip of the catheter in a container with fixative**. From 10 to 30 minutes may be needed to collect 5 to 10 ml of urine necessary for diagnosis. Although the procedure may be tedious to the patient, it is quite efficient in localizing the lesion.

P.746

The Direct Brushing Procedure

This procedure is used in the **investigation of space-occupying lesions in the ureters or renal pelves**. Brushing is performed through a ureteral catheter. The indications are the same as listed for retrograde catheterization.

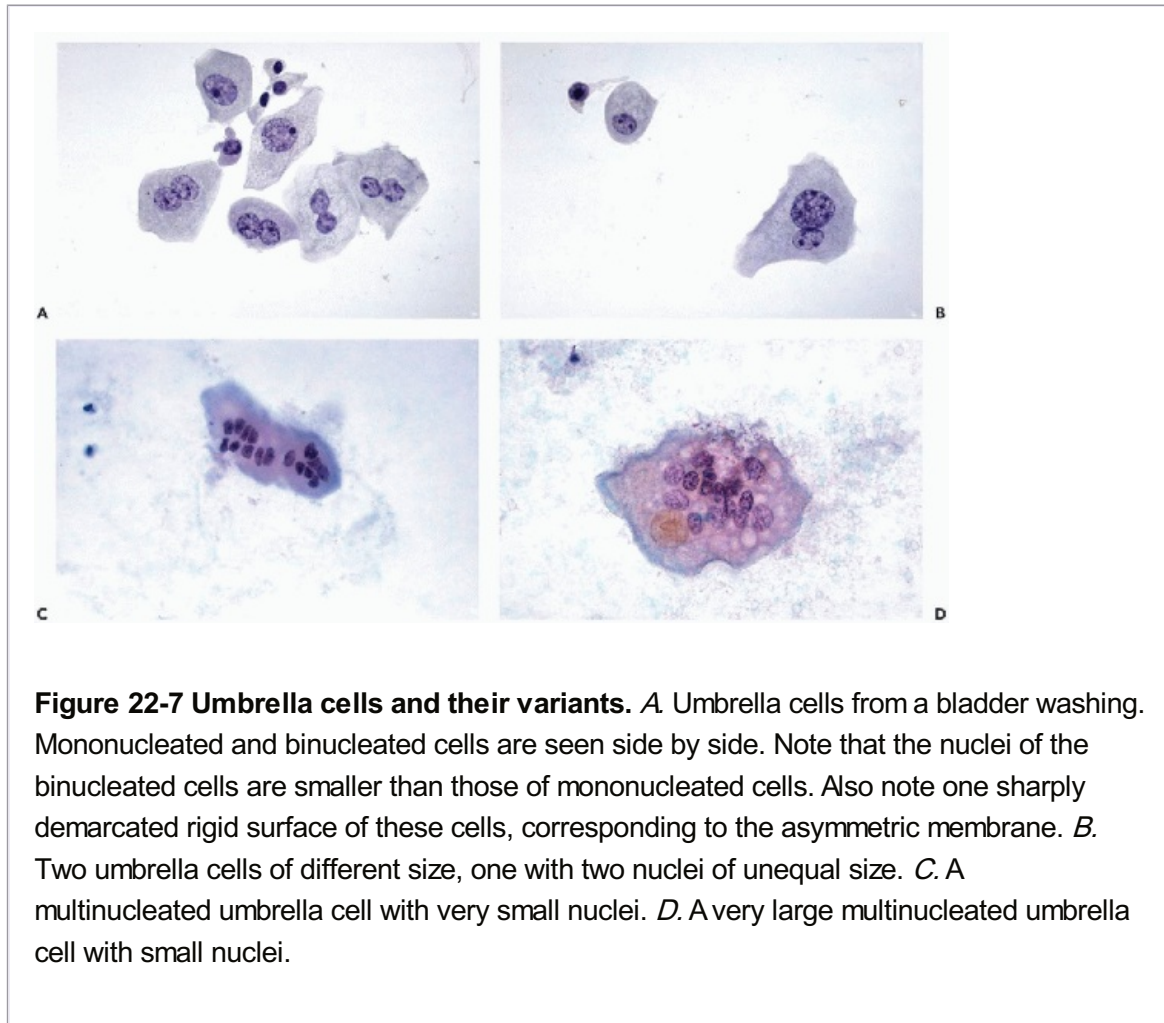

Processing of Direct Samples

Bladder washings or barbotage specimens may be processed in a manner similar to voided urine, discussed above. **Retrograde catheterization specimens**, if liquid, are processed in a similar manner. **Direct brush specimens** are usually prepared in the cystoscopy suite by the urologist and submitted as **smears**. For **optimal preservation, the smears** should be immediately fixed in 50% ethanol for at least 10 minutes. Alternatively, the **brushes can be placed in a 50% alcohol fixative** and forwarded to the laboratory for further processing. See Chapter 44 for further comments on processing of this material.

Cellular Components of the Urinary Sediment

An **understanding of the complexities of the normal cell population** of the urinary sediment under various clinical circumstances is an **important first step for proper diagnostic utilization of cytology of the urinary tract**. **Methods of sample collection and processing have a major impact on the interpretation of the cytologic images**. As always, information on **clinical circumstances** and **clinical procedures** leading to the collection of the cytologic samples may prevent major errors of interpretation, particularly in

low-grade urothelial tumors.

The urinary sediment contains:

- Cells derived from the urothelium and its variants
- Cells derived from renal tubules
- Cells derived from adjacent organs
- Cells extraneous to the urinary tract, such as macrophages and blood cells

Normal Urothelial Cells

Normal urothelial cells have several features that set them apart from other epithelial cells. The **cells vary greatly in size**: the superficial umbrella cells are often very large and may contain multiple nuclei, whereas epithelial cells from the deeper layers of the urothelium are much smaller and usually have a single nucleus. Another important general feature of urothelial cells is their tendency to desquamate in **large, complex clusters, particularly after instrumentation**.

P.747

It must be stressed, once again, that **the appearance of the sediment varies according to the method of collection**.

Superficial Umbrella Cells

The **size of the umbrella cells is variable** and depends to some extent on the number of nuclei. The average **mononucleated umbrella cells** measure from **20 to 30 μm in diameter** and, hence, are much larger than the cells from deeper epithelial layers (see below).

Multinucleated umbrella cells may be **substantially larger** (Fig. 22-7). These cells are usually **flat and polygonal** and usually have one **sharply demarcated, and sometimes angulated, surface**. The **abundant cytoplasm is thin and transparent, sometimes faintly vacuolated**, and may contain **fat** (Masin and Masin, 1976) or **mucus-containing vacuoles** (Dorfman and Monis, 1964). Sometimes, the nature of the vacuoles cannot be ascertained (Fig. 22-8A).

The **nuclei** also vary in size. In **mononucleated cells**, the **spherical or oval nuclei** may measure from **8 to 20 μm in diameter**, depending on the size of the cell. The large nuclei reflect a tendency of urothelial cells to form **tetraploid** or even **octaploid nuclei** (Levi et al, 1969; Farsund, 1974). This tendency to polyploidy appears to be part and parcel of the pattern of normal urothelial differentiation but its mechanism is unknown. These features of normal umbrella cells are important in DNA measurements (Wojcik et al, 2000). In well-preserved umbrella cells, the nuclei are **faintly granular but may contain prominent basophilic chromocenters** that should not be **confused with large nucleoli**. Using some of the **newer methods of semiautomated processing the chromocenters may be eosinophilic**, accounting for additional difficulties in the interpretation of the samples (Fig. 22-8B). **In some samples processed by commercial methods, we have observed peculiar condensation of nuclear chromatin, mimicking mitotic figures** (Fig. 22-8C).

Figure 22-8 Variants of superficial urothelial cells. *A.* Urothelial cell with multiple small cytoplasmic vacuoles and nuclear modification of unknown significance. *B.* An umbrella cell with an exceptionally large nucleus containing multiple eosinophilic chromocenters that should not be mistaken for nucleoli. *C.* High magnification of urothelial cells with peculiar condensation of chromatin, which in the larger cell mimics a mitotic figure, probably a processing artifact (ThinPrep). *D.* Multinucleated umbrella cells with pyknotic, degenerated nuclei.

Multinucleated umbrella cells also vary in size. Most cells are binucleated and contain either nuclei of normal size and configuration or smaller. Other cells have **multiple nuclei of variable sizes** (see Fig. 22-7C). **Large and small nuclei often** occur side by side within the same cell. Still other umbrella cells may contain **10 or more small nuclei** and appear as multinucleated giant cells (see Fig. 22-8C,D). Umbrella cells derived directly from **the ureters** are often much larger with many more nuclei than in cells derived from the bladder. Occasionally, the nuclei in the large superficial cells are **clumped and degenerated and may be mistaken**

P.748

for nuclei of cancer cells, an important source of diagnostic error (see Fig. 22-8D).

Cells from the Deeper Layers of the Urothelium

Urothelial cells originating in the deeper layers of the urothelium, are rarely seen in voided urine, but are common in specimens obtained by or collected after instrumentation. These cells are much smaller than umbrella cells and are **comparable in size to small parabasal cervical squamous cells** and unlike the superficial cells, **show little variation in size**. When fresh and well preserved, these cells have **sharply demarcated transparent cytoplasm** that is often **elongated and whip-shaped** when the cells are removed by instruments. The cytoplasm is stretched at points of desmosomal attachments to neighboring cells, a phenomenon also observed in metaplastic cervical cells (see Chap. 8). The **finely granular nuclei may contain single chromocenters, mimicking nucleoli** (Fig. 22-9A,B). **Occasionally, the nuclei may be pyknotic, particularly in brushings** (Fig. 22-9C). **Similar cells in voided urine may have pale, transparent nuclei. Occasionally, mitotic figures may be noted, particularly in urinary sediment obtained after a diagnostic or therapeutic surgical procedure** (Fig. 22-9D).

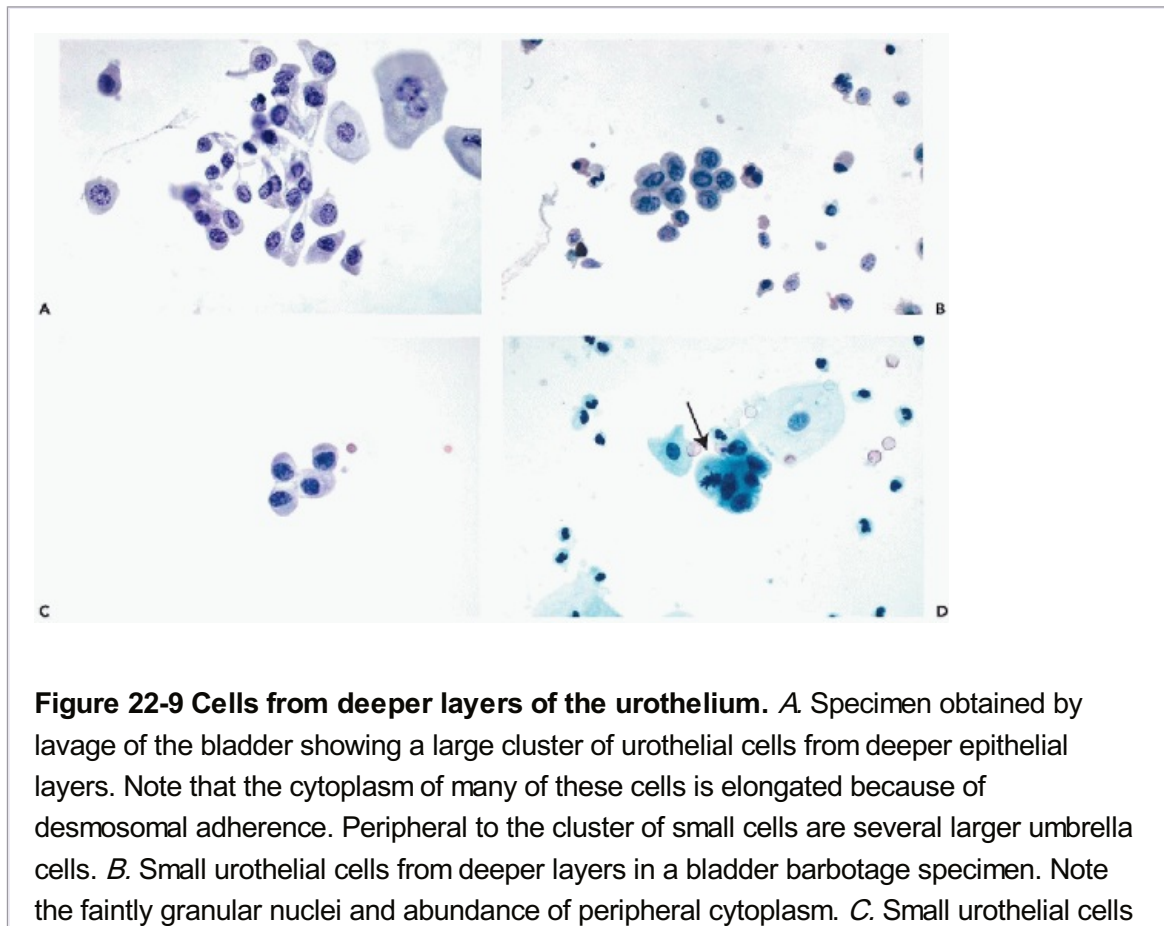

Figure 22-9 Cells from deeper layers of the urothelium. *A* Specimen obtained by lavage of the bladder showing a large cluster of urothelial cells from deeper epithelial layers. Note that the cytoplasm of many of these cells is elongated because of desmosomal adherence. Peripheral to the cluster of small cells are several larger umbrella cells. *B* Small urothelial cells from deeper layers in a bladder barbotage specimen. Note the faintly granular nuclei and abundance of peripheral cytoplasm. *C* Small urothelial cells

from deep epithelial layers in a specimen of retrograde brushings of the ureter. *D.* Small urothelial cells showing mitotic activity (*arrow*). This specimen was obtained 3 days after transurethral resection of the prostate.

Clusters of Urothelial Cells

A very important feature of normal urothelium is its propensity to desquamate in fragments or clusters that are sometimes very complex. Although this feature is markedly enhanced in urine samples obtained by bladder catheterization, lavage, or any type of instrumentation, urothelial cell clusters may also occur in spontaneously voided urine. It appears that even abdominal palpation, the slightest trauma, or inflammatory injury to the bladder may enhance the shedding of clusters. The clusters may be small and flat, composed of only a relatively few clearly benign cells (Fig. 22-10A), or much larger and composed of several hundred superimposed cells. The clusters may round up and appear to be spherical, oval, or “papillary” in configuration (Fig. 22-10B). Occasionally, they are more complex (Fig. 22-10C) and sometimes distorted during smear preparation. The distortion

P.749

may be increased if frosted slides are used. The periphery of such clusters should be carefully examined under high magnification of the microscope. **On close inspection, the edge of the clusters is sharply demarcated, and the normal component cells of the urothelium may be readily observed** (Fig. 22-10D). It must be noted that in urine sediment prepared by the **ThinPrep method**, nuclear chromocenters sometimes stain pink or red and thus may be considered to be “atypical” or even malignant. **It is paramount in urinary cytology to avoid making the diagnosis of a papillary tumor based on the presence of clusters.** For further discussion of cytology of bladder tumors, see Chapter 23.

Figure 22-10 Clusters of benign urothelial cells. *A.* A cluster of approximately papillary configuration composed of small epithelial cells from the deeper epithelial layers. *B.* A cluster of large urothelial cells with umbrella cells at the periphery (high power). Note the spherical “papillary” structure of the cluster, a formation caused by contraction of

muscularis mucosae, which may be seen as an eosinophilic structure in the center of that cluster (*arrow*). *C*. A large cluster of superficial and deep urothelial cells seen in a retrograde catheterization specimen. *D*. A large cluster of large and small urothelial cells in a lavage specimen of left kidney.

Cytologic Expressions of Epithelial Variants

It has been pointed out above that several epithelial variants may occur in bladder epithelium.

Intestinal-type epithelium may be the source of columnar, sometimes mucus-producing cells that are found in bladder washings and catheterized specimens but are uncommon in voided urine (Fig. 22-11A). These cells have a generally clear cytoplasm and spherical, finely granular small nuclei. Harris et al (1971) first described **ciliated columnar cells** in bladder washings (Fig. 22-11B).

There are no specific cytologic findings corresponding to Brunn's nests and cystitis cystica. Dabbs (1992) published his observations in renal pelvic washings in a case of **pyelitis cystica** but the findings, as illustrated, showed only clusters of normal urothelial cells.

Squamous epithelium sheds squamous cells of various degrees of maturity (Fig. 22-11C). The finding is **exceedingly common** and normal in adult women but is somewhat less frequent in men. In women, the urinary sediment may be used to assess their hormonal status ("**urocytogram**"), as discussed in Chapter 9. In both sexes, the harmless **squamous epithelium may become fully keratinized (leukoplakia)**, presumably as a consequence of chronic irritation. The cytologic findings and significance of leukoplakia of the bladder are discussed below.

Renal Tubular Cells

Renal tubules are lined by a single layer of epithelial cells that vary somewhat in configuration according to the segment of the tubule. Of special interest in urine cytology is the terminal part of the tubular apparatus or the **collecting**

P.750

ducts, lined by a single layer of cuboidal to columnar epithelial cells with clear cytoplasm and small spherical nuclei. These cells may be observed in the urinary sediment under various circumstances.

Figure 22-11 Variants of urothelial cells. *A.* Columnar urothelial cells in a bladder lavage. *B.* Small columnar cell with ciliated surface. *C.* Intermediate squamous cells. *D.* Renal tubular cells surrounding an umbrella cell. Note the small size, pyknotic nuclei, and granular cytoplasm of the tubular cells (*arrows*). Also present in this same field are a few granular casts (*arrowheads*).

Renal tubular cells may be numerous whenever there is some **insult to the renal parenchyma**, for example, after an **intravenous pyelogram**. They may be found after an episode of **hematuria or hemoglobinuria**. The small cells are **poorly preserved, cuboidal or columnar in shape**, and are characterized by **small pyknotic nuclei and granular cytoplasm** (Fig. 22-11D). The presence of numerous, well-preserved tubular cells is of importance in monitoring renal transplant patients (see below). The renal tubular cells have **phagocytic properties** and may store the **dyes** used in intravenous pyelography, which are visualized as a yellow pigment in the cytoplasm. Khalil et al (1999) described **large, vacuolated renal tubular cells** with some similarity to macrophages, in the voided urine sediment of a patient with a rare disorder, **osmotic nephrosis**. The patient was treated with intravenous immunoglobulins stored in the cytoplasm. The identity of the cells was confirmed by immunochemistry and electron microscopy. **The presence of renal tubular cells in the urinary sediment must be correlated with clinical circumstances and does not necessarily indicate the presence of a renal disorder.**

Renal Casts

Accumulation of various proteins, erythrocytes, leukocytes, necrotic cells, and cellular debris **molded into longitudinal cylindrical structures** are known as **renal casts**. It is often assumed that the presence of casts indicates a severe renal disorder. However, carefully collected and fixed urinary sediment samples often reveal renal casts in the absence of disease.

In voided urine specimens collected in a 2% polyethylene glycol (Carbowax) solution in 70% ethanol (Bales, 1981; see Chap. 44), **renal tubular cells and casts are well preserved and observed with unexpected frequency, even in patients without overt evidence of renal**

pathology.

The **renal tubular casts** are either **hyaline or granular**. The **hyaline casts** are composed of **homogeneous eosinophilic protein material**, sometimes with a few renal tubular cells attached at the periphery (Fig. 22-12A). The **granular casts** are composed of **cell debris mixed with degenerating renal tubular cells** with granular cytoplasm (Fig. 22-12B; see also Fig. 22-11D). Such casts are very common in renal transplant patients during episodes of rejection (see below) but may also be observed after urography during the period of elimination of the dye (Fischer et al, 1982). The presence of casts must be correlated with clinical data as it may indicate the presence of a renal parenchymal disorder.

P.751

Figure 22-12 Renal casts. A. Hyaline cast. B. Tubular, granular cast (compare with Fig. 22-11D).

Cells Originating in Adjacent Organs

Cells from the Prostate, Seminal Vesicles, and Testis

These cells may be observed in the sediment of voided urine **after a vigorous prostatic palpation or massage**. The dominant component of such specimens are usually **spermatozoa** and their precursor cells, including **spermatogonia**, characterized by larger dark nuclei. The **normal prostatic glandular cells are difficult to recognize** as they are small and have few distinguishing characteristics. By far, the most important cells in such sediments are **cells derived from seminal vesicles**, which are **large and may have large, irregular, hyperchromatic but homogeneous nuclei, mimicking cancer cells**. They are almost invariably degenerated when expelled and are recognized by the presence of **yellow cytoplasmic lipochrome granular pigment**. For further description of these cells in health and disease, see Chapter 33.

Cells From the Female Genital Tract

The urinary stream may pick up cells from the vagina and the vulva. The most common are **normal squamous cells** (see above), **but abnormal cells reflecting neoplastic processes in the female genital tract may also occur** (see Chap. 23).

Other Cells

Blood Cells

Besides the urothelial and squamous cells, the normal urinary sediment may contain a few **leukocytes**. It is generally assumed that normal urinary sediment does not contain any red blood cells. Yet Freni (1977), using a careful collection technique, documented that **a few erythrocytes may be observed in virtually all healthy adults**. In 8.8% of this healthy population, there were 10 erythrocytes per single, high-power field. These observations were important because the presence of microscopic blood in urine has been suggested as a means of detecting bladder tumors.

Microhematuria

Microhematuria is by definition, the presence of erythrocytes in urine. Because normal people may show up to 10 erythrocytes per high-power field, the diagnosis should not be rendered unless the number of erythrocytes is higher. Cohen and Brown (2003) proposed a much lower threshold for the diagnosis of microhematuria, namely two erythrocytes per high-power field or a positive dipstick evaluation for hemoglobin. Microhematuria in asymptomatic persons has been the subject of several studies. Unfortunately, the populations studied were different and therefore no simple conclusion can be drawn. In an earlier study by Greene et al (1956), 500 Mayo Clinic patients with microhematuria were investigated and 11 of them were found to have cancer (7 of bladder and 2 of kidney). Most other patients had trivial and incidental disorders. In a study by Carson et al (1979) of 200 Mayo Clinic patients referred for a urologic workup, 22 (11%) had a tumor of the bladder and 2 had carcinoma of the prostate. It is of note in the Carson study, that **synchronous cytologic examination of urine was positive in 9 patients with occult carcinoma in situ and negative in 5 patients with low-grade papillary tumors** (see Chap. 23). On the other hand, in a study of **1,000 asymptomatic male** Air Force personnel, Froom et al (1984) found **microhematuria in 38.7%**. In only one subject, a "transitional cell carcinoma," not further specified, was observed. In a randomized 1986 study, Mohr et al observed microhematuria in 13% of asymptomatic adult men and women, with neoplasms of the bladder in 0.1 % and of the kidney in 0.4% of the population studied. Bard (1988) observed no significant disease in 177 women with microhematuria, followed for more than 10 years.

The initial views on the significance of microhematuria suggested an aggressive investigation of all patients with this disorder. More recent opinions, notably by Mohr et al, Messing et al (1987), Bard (1988), and Grossfeld et al (2001) suggest that a **conservative follow-up of most asymptomatic patients is appropriate**, with cystoscopic work-up reserved for the patients with persisting significant hematuria or other evidence or suspicion of an important urologic disorder. Carson's study suggests that a **cytologic follow-up** may be helpful in some patients. Similar guidelines were more recently proposed by the American Urological Association (Grossfeld et al, 2001).

As Messing et al (1987) noted, microhematuria is a sporadic

P.752

event that may occur intermittently and may not occur at all in patients with significant disease. Therefore, it seems quite unlikely that microhematuria may be used as a screening test for bladder tumors.

Renal versus Nonrenal Origin of Erythrocytes

The issue of differentiation of microhematuria caused by parenchymal renal disease, such as

glomerulonephritis, versus microhematuria of other origin is controversial. Rathert and Roth (1991) suggested that a microscopic examination of either very fresh or rapidly fixed voided urine sediment does allow the separation of the two cell types. In phase microscopy, erythrocytes of renal origin were characterized by a **dense periphery in the form of a double ring, and an “empty” center**. Another manifestation of renal hematuria may be **partial breakdown of erythrocytes with the appearance of small, irregular, oddly shaped cells**. Other extrarenal erythrocytes acquire features akin to poikilocytosis, with the **periphery of the erythrocytes covered with spike-like excrescences or spherical protrusions**.

Mohammed et al (1993) and Van der Snoek et al (1994) (among others) suggested that the presence of “**dysmorphic” erythrocytes**, that is erythrocytes with abnormalities of shapes, was suggestive of a renal parenchymal disorder, whereas “**isomorphic erythrocytes** (i.e., red blood cells of normal shape) were representative of nonrenal origin of hematuria. Mohammed, using phase microscopy, indicated that the cut-off point of 20% of dysmorphic erythrocytes had a sensitivity of 90% and specificity of 100%. Van der Snoek used a cut-off point of 40%, achieving a sensitivity of 66.7%. The specificity of these observations was debated, among others, by Pollock et al (1989), Favaro et al (1997), Zaman and Proesmans (2000). Most recently, Nguyen (2003) examined the urinary sediments in 174 patients with various forms of glomerular disease and observed doughnut-shaped, target- or bleb-forming erythrocytes (collectively named **G1 or GIDE cells**) in a substantial proportion of cases. Nguyen proposed that the presence of GIDE cells above 10% of the erythrocyte population was a “specific diagnostic marker for glomerular disease.” Unfortunately, the study did not include control patients with other possible causes of microhematuria and, thus, its specificity must still be proved.

Eosinophiluria

The presence of **bilobate eosinophils** in urine may be an indication of a drug-induced or spontaneous eosinophilic cystitis (see below). Nolan et al (1986) suggested the use of **Hansel's stain** (methylene blue and eosin-Y in methanol) to facilitate the recognition of eosinophils.

Acellular Components

Crystals

Urate crystals are commonly seen in poorly fixed urine specimens. The precipitation of urates occurs with a change in the pH of the urine, usually occurring after collection. The **crystals are usually semi-transparent, of odd shapes, and have no diagnostic significance**, except that they may completely obscure cells present in the specimen. **Triple phosphate** crystals are transparent, often rectangular. **The star-like uric acid crystals** derived from stones, are rarely seen. From time to time, other crystals may be observed, such as the needle-like crystals of tyrosine or **hexagonal crystals of cystine**. Certain drugs, notably sulfonamides, may also form crystals of specific configuration. The reader is referred to Naib's book (1985) for a detailed description of uncommon crystals observed in the urinary sediment.

Renal casts were discussed above.

Contaminants

Urinary samples may sometimes contain **surgical powder** in the form of crystalline precipitates. Cotton threads may also occur. Occasionally, the **brown, septated fungus of the**

species *Alternaria*, a contaminant from the water supply, may be observed. For a description and illustrations of this fungus, see Chapter 19.

COMPOSITION OF NORMAL SEDIMENT OF URINE SAMPLES ACCORDING TO THE MODE OF COLLECTION

Voided Urine

In normal, spontaneously voided urine, the background is clean, with only an occasional erythrocyte or leukocyte. (Table 22-3)There are usually few urothelial cells, occurring singly and in small clusters. An occasional large umbrella cell may be noted but most urothelial cells are small. The nuclear structure of these cells is rarely well preserved and most nuclei appear spherical, pale and bland, although an occasional pyknotic or apoptotic nucleus may be noted.

Squamous cells, usually of superficial type, are commonly present and are usually more numerous in females than in males. In males, the squamous cells are of urethral origin. In the female, some of the cells represent vaginal contamination and some are derived from the vaginaltype epithelium in the area of the trigone commonly observed in normal women (see above). The value of urinary sediment in estimating the hormonal status of the woman (urocytograms) is discussed in Chapter 9.

In newborn children, regardless of sex, the urinary sediment may contain a fairly large proportion of mature squamous cells, reflecting the effect of maternal hormones.

Catheterized Bladder Urine

Because catheters can damage the epithelium, catheterized bladder urine is usually much richer in urothelial cells than voided urine. The single cells, which may vary enormously in size and configuration, reflect the entire spectrum of urothelial cells ranging from the large umbrella to smaller cells from the deeper layers of the urothelium. Variants of the urothelium, particularly columnar cells are commonly present. Of special significance are clusters of urothelial cells that may be “papillary” or complex, as shown in Figure 22-10, in the absence of tumors.

P.753

TABLE 22-3 PRINCIPAL CYTOLOGIC FEATURES OF URINARY SEDIMENT ACCORDING TO METHODS OF COLLECTION					
	Voided Urine	Catheterized Urine	Bladder Washings	Retrograde Catheterization	Brushings
Urothelial cells	sparse, poorly preserved	more numerous, sometimes in clusters	broad variety of urothelial cells, singly and in	as in bladder washings: complex clusters and umbrella cells*	numerous umbrella cells and complex clusters*

			clusters*		
Squamous cells	common in adults and newborns of both sexes	rare	rare	absent	absent
Renal tubular cells and casts	common	rare	absent	absent	absent
Contaminants	common	rare	absent	absent	absent

* Important source of diagnostic error.

Bladder Washings (Barbotage)

These specimens offer an excellent panorama of the component cells of the **urothelium**, as discussed above. A broad variety of superficial umbrella cells and deeper urothelial cells and their variants may be seen. Cell clusters of various configurations are common and may be numerous.

Retrograde Ureteral Catheterization

Retrograde catheterization requires **threading a small catheter through the narrow lumens of the ureters**. Inevitably, the tip of the catheter dislodges urothelial cells from their setting, resulting in **specimens characterized by a large number of cell clusters next to single urothelial cells of a large variety of types**. It has been mentioned above that umbrella cells with a very large number of nuclei are particularly common in such specimens.

The cell **clusters** may be **numerous** and sometimes several dozen of them may be observed in a single specimen. **The multilayered, complex configuration of some of the clusters and their role as a source of false-positive reports has been stressed above**. An example of such an error seen by us in consultation is shown in Figure 22-13. In this case, the clusters were **misinterpreted as a "papillary tumor"** and the diagnosis was followed by a nephroureterectomy 4 days later. There was no evidence of a tumor. In the histologic sections of the ureter, the origin of the clusters could be traced to the large segments of the denuded urothelium scraped by the tip of the catheter. On review of the cytologic sample, the component cells of normal urothelium could be readily observed.

Brushings of Ureters and Renal Pelves

The samples, when prepared as **direct smears** by the urologist, are often of **limited diagnostic value** because of drying artifacts. The interpretation of numerous, **thick clusters of urothelial cells** is very difficult. We have seen several cases wherein the clusters were mistaken for evidence of a papillary tumor (see Fig. 22-13). Otherwise, the cytologic findings

are very similar to those described for retrograde catheterization.

It is a safe rule in diagnostic cytology of the urinary tract that in the absence of clear-cut criteria of cancer, such as a markedly altered nucleocytoplasmic ratio and changed nuclear configuration and texture (described in detail in Chapter 23), **one should not attempt the diagnosis of a malignant tumor.** This is particularly important with specimens obtained by brushing, retrograde ureteral catheterization or immediately thereafter, after instrumentation such as cystoscopy, or in bladder washings obtained under cystoscopic control. It is essential to be familiar with the enormous morphologic variability of the normal urothelial cells, which may exhibit chromocenters mimicking large nucleoli.

INFLAMMATORY PROCESSES WITHIN THE LOWER URINARY TRACT

Bacterial Infections

Bacterial infections involving the lower urinary tract may be **primary or secondary, acute or chronic.** The most common are **cystitis and pyelonephritis**, which are usually caused by a **bacterial infection.** Both disorders may cause high fever and **severe pain** in the lower abdomen, radiating to the groin. The histologic changes may include ulceration of the epithelium and infiltration of the wall of the organ by granulocytes in the acute phase and lymphocytes in the chronic phase. A variety of **pyogenic bacteria**, especially **cocci** but also ***Escherichia coli*** and ***Pseudomonas aeruginosa* (*Bacillus pyocyaneus*)**, may be the predominant organisms. Wu et al (1996) documented that adhesion of *E. coli* to the urothelial surface is mediated by uroplakins.

In most cases, the bacterial infections are acute but may become chronic. **Of special significance are infections with gram-negative organisms occurring in debilitated patients who may develop septicemia, followed by irreversible**

P.754

shock leading to death. Occasionally, the offending organism may be observed in the urinary sediment and classified as bacillary or coccoid, but its exact identification must depend on bacteriologic data.

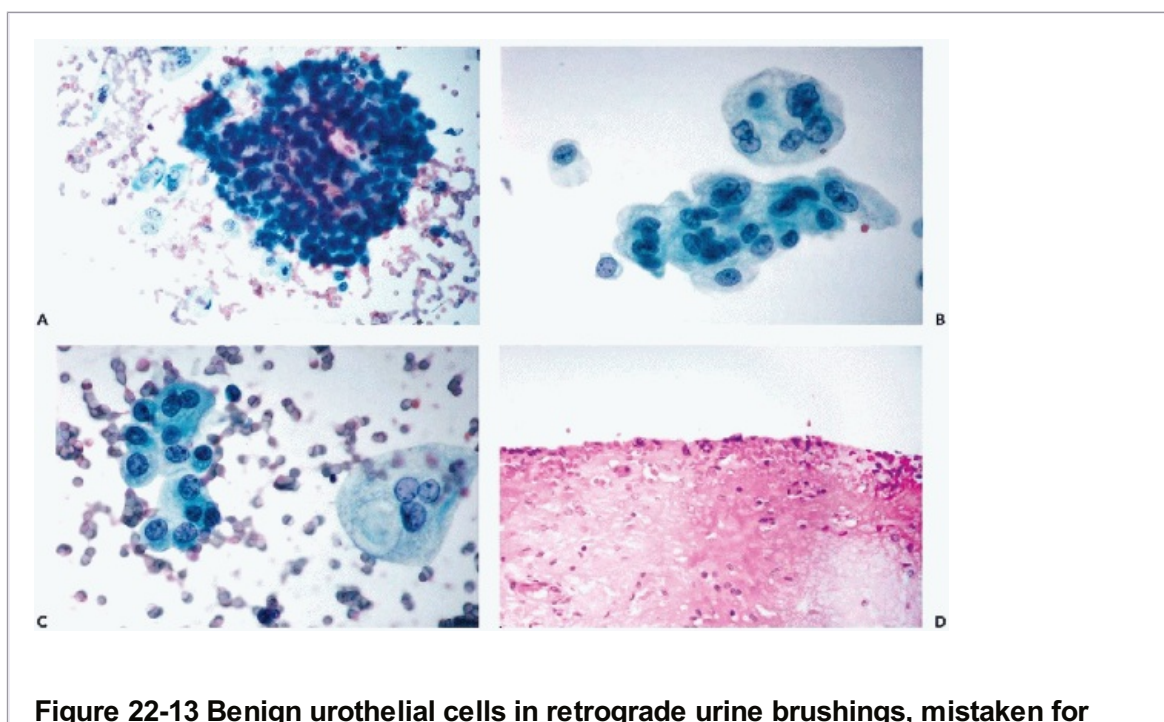

Figure 22-13 Benign urothelial cells in retrograde urine brushings, mistaken for

cells of a papillary tumor. A-C. All three fields show large clusters of benign urothelial cells (A is overview). D. Surface of the ureter removed 3 days after the diagnosis of a "papillary tumor." The surface of the ureter was denuded by the brush.

Contributory Factors

Obstructive processes, such as **strictures, compression, calculi, diverticula, or prostatic enlargement** that interfere with the free flow of urine, are common factors contributing to infection. **Cancers, intrinsic or extrinsic** to the lower urinary tract, may also create a favorable terrain for infection or may produce obstruction with the same effect. In **women, infections of the lower genital tract** may spread to the urethra and bladder. **Therapeutic procedures, such as in-dwelling catheters, particularly with inadequate toilette, may lead to severe infections, including the feared gram-negative septicemia.**

Some of the long-standing infectious processes are secondary to generalized infections. For instance, **tuberculosis of the bladder is usually secondary to pulmonary and renal tuberculosis.** Still, changes **mimicking tuberculosis** can be induced by treatment with Bacillus Calmette-Guérin (BCG), as described below.

Cytology

The background of the urinary sediment in acute inflammation shows **red blood cells and purulent material.** The latter shows **necrotic debris** and numerous **polymorphonuclear leukocytes** or, in more chronic forms of infection, numerous **lymphocytes.** The epithelial cells, singly and in clusters, typically are increased in number in the urine but the cells are often concealed by a heavy inflammatory exudate. **Degeneration and necrosis are the characteristic cellular changes in epithelial cells** (Fig. 22-14A,B). The degenerated cells are of variable size and configuration and are often **enlarged** because of markedly **vacuolated cytoplasm** that may be infiltrated with polymorphonuclear leukocytes (Fig. 22-14C). Of special diagnostic interest are the **nuclei** of the urothelial cells. They may be of somewhat **variable sizes and of irregular outline, but usually show an opaque or clear, transparent center surrounded by a rim of chromatin.** This is an important point of differential diagnosis between inflammatory atypias and urothelial cancer. In the latter, the nuclear texture is quite different (see Chap. 23). Occasionally, the nuclei of urothelial cells may show **chromatin condensation (pyknosis) and apoptosis**, that is, fragments of chromatin contained within the nuclear membrane. Contrary to cancer cells, the **nucleocytoplasmic ratio** in such cells is usually normal.

Other Cells Seen in Inflammation

Macrophages may make their appearance in the urine in varying numbers, indicating a more chronic inflammatory

P.755

process. They include **mononucleated or multinucleated varieties, with faintly stippled spherical or kidney-shaped (remiform) nuclei, and characteristic faintly vacuolated basophilic cytoplasm, often showing evidence of phagocytosis.** They may be confused with vacuolated urothelial cells. Occasionally, **plasma cells** may be noted. In eosinophilic cystitis (see below), eosinophils may appear in the urinary sediment.

Figure 22-14 Urine sediment in inflammation. *A.* A low-power view of urine sediment containing numerous leukocytes. *B.* Poorly preserved urothelial cells surrounded by leukocytes and macrophages. Note the presence of nucleoli, possibly indicating a “repair” reaction. *C.* A cluster of urothelial cells with the cytoplasm infiltrated by polymorphonuclear leukocytes. *D.* Poorly preserved urothelial cells in the presence of an inflammatory exudate.

Specific Forms of Inflammation

Granulomatous Inflammation

Tuberculosis

Kapila and Verma (1984) described the presence of **commashaped epithelioid cells** in the urinary sediment of a patient with tuberculosis of the bladder. The slender, carrot-shaped cells forming a tubercle are characteristic, if present. Pisciole et al (1985) described the cytologic findings in the urinary sediment of 11 patients with tuberculosis. In 5 of them, he reported finding epithelioid cells, although the illustration provided was not convincing. In all 11 patients, **multinucleated cells of Langerhans' type** were observed. In my experience, this type of giant cell is extremely rare in urinary sediment and its presence has yet to be proven to be of diagnostic value. Pisciole et al also described in 2 patients the presence of markedly atypical urothelial cells resembling cancer cells, which they traced to atypical hyperplastic urothelium that was similar to flat carcinoma in situ.

Granulomas after Bladder Surgery

Spagnolo et al (1986) described the presence of granulomas in the bladder walls of patients with two or more surgical procedures for bladder tumors. There were **two types of granulomas**; one type with **necrosis and palisading of peripheral cells resembling rheumatoid nodules**, and the other type was composed of **foreign body giant cells**. There is no known cytologic presentation of these granulomas and the entity is cited as a potential source of confusion with tuberculosis.

Inflammatory Pseudopolyp

A chronic inflammatory process in the bladder may result in a **protrusion of bladder epithelium around an inflamed stroma, mimicking a neoplastic lesion** on cystoscopy. Similar lesions were recently described in renal pelvis (Leroy et al, 2000). The urothelial cells in the urinary sediment show minor changes consistent with inflammation.

P.756

Interstitial Cystitis (Hunner's Ulcer)

This is a rare form of chronic ulcerative cystitis of unknown cause, first described by Hunner (1915) and extensively discussed by Smith and Denner (1972) and by Sant (1997). In an elaborate discussion, Elbadawi (1997) reported that ultrastructural studies of artificially distended bladders supported the hypothesis that altered nerve supply in the wall of the bladder may be the cause of this disorder. The disease causes painful cramping and high frequency of voiding. We studied the urinary sediment in several patients with this disorder, but except for evidence of inflammation, found **no specific cytologic abnormalities of note**. Dodd and Tello (1998) confirmed the absence of specific cytologic changes in this disorder, noting only acute inflammation with polymorphonuclear leukocytes and eosinophiles. Utz and Zincke (1973) pointed out that **nonpapillary carcinoma in situ may masquerade clinically as interstitial cystitis**. The cytologic presentation of carcinoma in situ is discussed in Chapter 23.

Eosinophilic Cystitis

Infiltration of the bladder wall with numerous eosinophils is most commonly observed **after cautery treatment** and may also occur in **patients with asthma or other allergic disorders**. **Spontaneous forms of eosinophilic cystitis may also occur** (Brown, 1960; Palubinskas, 1960; Hellstrom et al, 1979). The disease may produce **thickening of the wall of the bladder, mimicking an invasive carcinoma** (Hansen and Kristensen, 1993) or **cause obstruction of the urinary outlet** (Case record of the Massachusetts General Hospital, case 27-1998). In all such cases, the **urinary sediment may contain numerous bilobate eosinophils**. For discussion of eosinophiluria, see above. A true **eosinophilic granuloma (Langerhans' cell granulomatosis)**, with simultaneous proliferation of eosinophils and macrophages, may also occur (Koss, 1975). For discussion of the cytologic presentation of eosinophilic granuloma, see Chapter 31.

Fungal Infections

The most common fungus observed in the urinary sediment is ***Candida albicans***. The organism is observed mainly as **fungal spores** (yeast form), but pseudohyphae may occasionally be observed (see Fig. 10-10). This infection is **particularly serious in renal transplant recipients and other immunosuppressed patients**. It may lead to generalized fungal infection and septicemia or, in a rare case, to obstruction of the ureters by a fungal ball. The presence of casts of candida indicates upper urinary tract (renal) infection with an ominous prognosis.

Other fungi are uncommon. Eickenberg et al (1975) pointed out that the urinary tract may be affected in patients with systemic ***North American blastomycosis*** and that the organism can be identified in urine (see Fig. 19-42). We have also observed ***Aspergillosis*** in the urinary sediment of a patient with AIDS (see Fig. 19-47). Mukunyadzi et al (2002) reported a case of

histoplasmosis diagnosed in urinary sediment. **Alternaria** species, a brown, septated fungus, is a common contaminant (see above and Fig. 19-18A).

Viral Infections

Cytomegalovirus (Cytomegalic Inclusion Disease)

This sometimes fatal, but fortunately uncommon, viral infection has been recognized in infants and children for many years. More recently, the frequency of cytomegalovirus (CMV) has increased in adults as a consequence of the acquired immunodeficiency syndrome (AIDS) and immunosuppression, notably in recipients of bone marrow or renal transplants, and patients with various forms of cancer. This virus has been identified in patients with **infectious mononucleosis and may survive in the seminal fluid, presumably in the spermatozoa** (Lang et al, 1974). **Sexual transmission of the virus to a young woman** has been recorded in this case. Urinary sediment remains one of the methods of diagnosis of this serious disorder.

As discussed at length in Chapter 19, this often deadly disease is due to a virus of the herpesvirus group. The **conclusive diagnosis** intra vitam is made by cytologic examination of gastric washings, sputum or other lung samples, or of the urinary sediment. Precise methods of diagnosis, based on molecular markers, are now available as well. The virus can also be demonstrated by in situ hybridization with appropriate probes.

The **identification of cytomegalovirus in the urinary sediment of infants and children, and now in high-risk adults, has been a recognized diagnostic procedure for many years.** Urothelial cells may show all stages of infection. In the **early stages, multiple, small, basophilic viral inclusions are distributed throughout the nucleus and the cytoplasm and are surrounded by individual halos.** In more advanced, classic forms of the disease, **the epithelial cells are markedly enlarged and carry within their nuclei very large, basophilic inclusions, surrounded by a conspicuous clear halo. The residual chromatin is condensed at the nuclear periphery** (Fig. 22-15A). In the advanced stage of the disease, **cytoplasmic inclusions are somewhat less frequent.** Cellular inclusions of cytomegalovirus have been observed in the urinary sediment of **renal transplant recipients** (Bossen et al, 1969; Johnston et al, 1969), in young **patients with leukemia** (Chang, 1970) and in immunosuppressed patients.

The **differential diagnosis of cytomegalovirus is with human polyomavirus**, as discussed below. Cytomegalovirus infection is now treatable with antiviral agents.

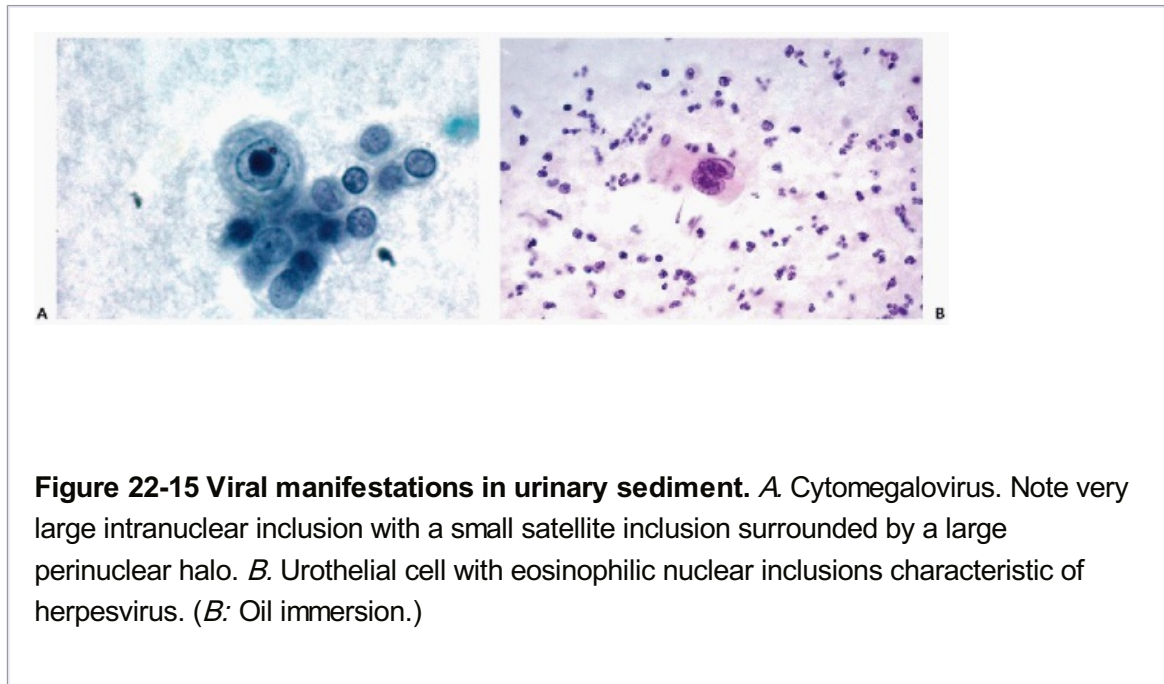

It is of particular interest that the **incidental identification of cytomegalovirus in otherwise healthy adults does not carry with it the ominous prognosis** of this disease as seen in infancy and early childhood or in immunoincompetent patients. Apparently, many of the patients are carriers of the virus without suffering any direct ill effect.

Herpes Simplex Virus

Herpetic infection of the urinary tract was a rarity in the past. The recognition of the **typical multinucleated epithelial cells with molded, ground-glass nuclei and, on rare**

P.757

occasions, of typical eosinophilic intranuclear inclusions has not posed any diagnostic dilemmas (Fig. 22-15B; also see Chaps. 10 and 19). This virus has been recognized in urinary sediment of **recipients of renal allografts** (Bossen and Johnston, 1975) and in a **patient with squamous cancer of the urinary bladder** (Murphy, 1976). Several such cases were

Human Polyomavirus (Decoy Cells)

Cytopathic changes induced by this virus in urothelial cells may be confused with cancer. This was first recognized in the 1950s, by the late Mr. Andrew Ricci, senior cytotechnologist at Memorial Hospital for Cancer in New York. He observed in the urinary sediment **cells with large, homogeneous, hyperchromatic nuclei, mimicking cancer cells, but not associated with bladder cancer** (Figs. 22-16A,B and 22-17A). Mr. Ricci named these cells **decoy cells**. The nature of the decoy cells remained unknown for many years. In the 1968 edition of this book, it was speculated that the change was due to an unidentified virus. This virus has been identified as **human polyomavirus** by Gardner et al (1971) and has been extensively studied by Coleman and her coworkers (1973, 1975, 1980, 1984). The virus belongs to the **Papovaviridae family** and is **related to the human papillomavirus**. Polyomaviruses have a somewhat smaller genome than the papillomaviruses and are somewhat differently organized (Frisque et al, 1984). **Electron microscopy** of nuclei containing polyomavirus inclusions shows many similarities to the human papillomavirus (HPV) infection (Fig. 22-18). Both viruses form **crystalline arrays of viral particles**. The polyomavirus particles are somewhat smaller than the papillomavirus particles.

Two strains of the human polyomavirus, both named after the initials of the patients, have been identified: the **JC strain**, isolated from a patient with the previously rare disease, **progressive multifocal leukoencephalopathy** (Pagett et al, 1971), and the **BK strain**, isolated from a **patient with a renal transplant** (Gardner et al, 1971). The two strains differ from each other by the size of the virus particles and by serologic characteristics. It was thought for many years that the **two viral types are limited to specific anatomic territories, that is, the JC virus to the brain and the BK virus to the urinary tract. This is no longer the case, as JC viruses have been documented in the urinary tract** by polymerase chain reaction (PCR) (Itoh et al, 1998).

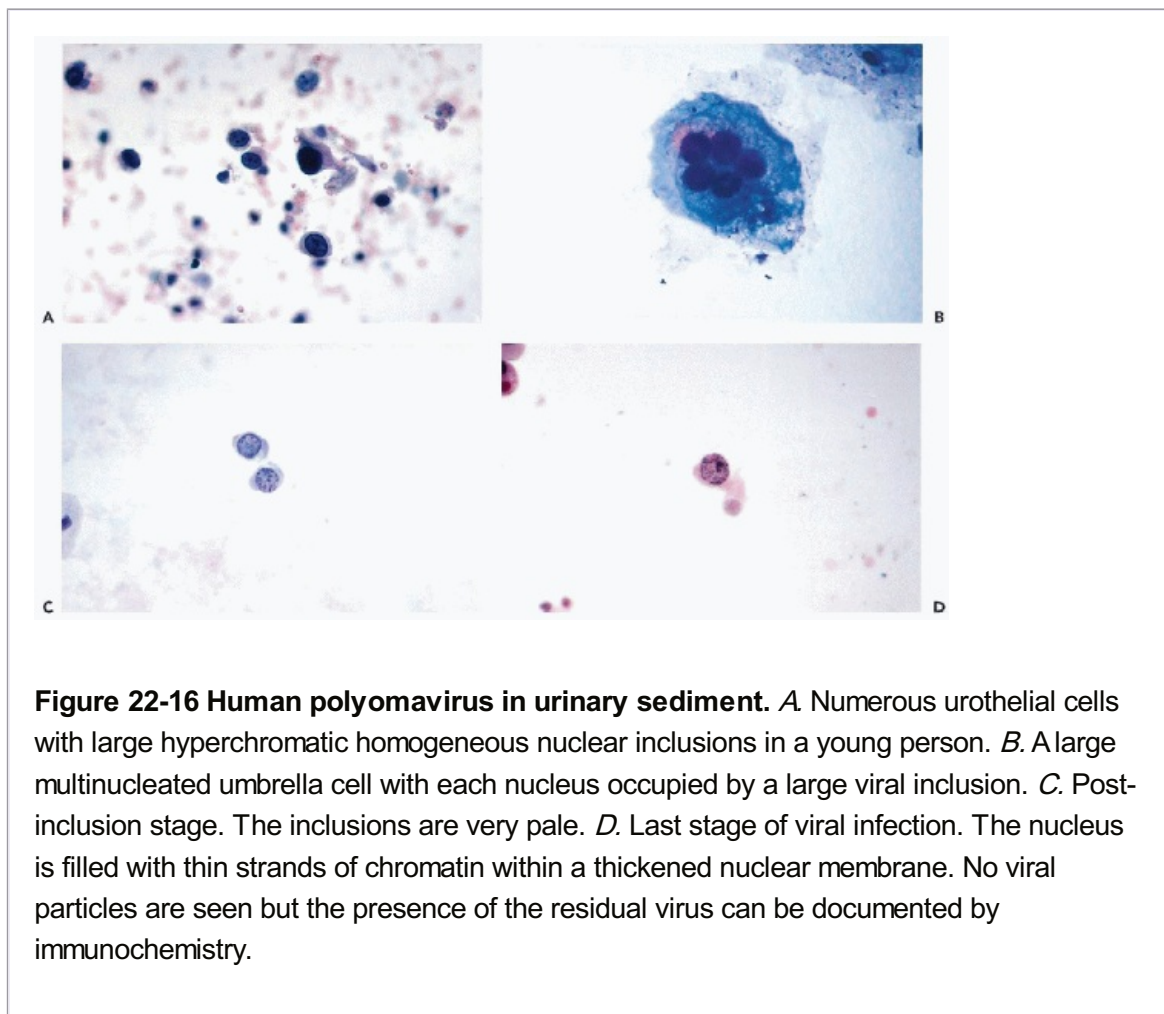

It has been documented by serologic studies that the **human infection with polyomaviruses is acquired in childhood and is nearly universal** (Padgett and Walker, 1976). **Thus, the**

cytologic manifestations of this infection reflect a reactivation of, or a superinfection with, the virus, a sequence of events also proposed for the human papillomavirus (Koss, 1989; see Chap. 11). There is, however, a major difference between these two viruses: the **human papillomavirus is implicated in neoplastic events** in the skin, female genital tract, larynx, the esophagus, and perhaps even the bronchus (see appropriate chapters), but **there is no evidence that the polyomavirus is carcinogenic in humans**, although it plays a role in tumor formation in experimental animals.

The **activation** of polyomaviruses occurs in **immunosuppressed individuals**, patients receiving chemotherapy, such as cyclophosphamide (Cytoxan, see below), in **diabetics**, in **organ transplant recipients** (O'Reilly et al, 1981; Apperly et al, 1987), and in patients with **AIDS** (Filie et al, 2002). **Most importantly, however, virus activation may occur without any obvious cause** (Kahan et al, 1980; Minassian et al, 1994) and **last for a few weeks or even months without any ill effects** (Table 22-4). In such cases, shedding of the affected epithelial cells may be **intermittent**.

The polyomavirus plays an important role in the previously very rare **progressive multifocal encephalopathy**, currently on the rise in AIDS patients. Viral inclusions occur in nuclei of oligodendrocytes (summary in Berger and Major, 1994). Houff et al (1988) documented that the **JC type polyomavirus may proliferate in bone marrow cells and in mononuclear cells**, which may carry the virus to the brain, causing this disease.

P.758

Perhaps the most significant new development in reference to human polyomavirus is its role in

interstitial nephritis in AIDS and in renal transplant patients (Rosen et al, 1983; Gardner et al, 1984; Drachenberg et al, 1999). It has been documented that **activation of the BK virus is a cause of renal dysfunction in patients with AIDS** (Nebuloni et al, 1999). **The same virus causes severe renal allograft dysfunction** that may result in graft rejection unless treated (Pappo et al, 1996; Drachenberg et al, 1999; Nিকেleit et al, 2000). Petrogiannis-Haliois et al (2001) reported a case of **polyomavirus vasculopathy** in a patient after renal transplant. In all these situations, **classical evidence of polyomavirus activation may be observed in the sediment of voided urine**, as described below (Fig. 22-19). Drachenberg et al (1999) considered the **examination of voided urine sediment as the most effective diagnostic test for polyomavirus in renal transplant patients**.

A case of **polyomavirus infection with ureteral obstruction** in a renal allograft recipient was reported by Coleman et al (1973) and the possibility that the virus contributed to the obstruction of the cystic duct in a liver transplant recipient has been raised. It is not known whether these events were actually related to human polyomavirus infection.

The suggestion by Arthur et al (1986) and Apperley et al (1987) that the virus is the cause of **hemorrhagic cystitis** in bone marrow transplant recipients, has been disproved. In a series of 17 bone marrow transplant patients monitored by urinary cytology, the **presence of the virus-induced changes in urinary sediment could not be correlated with hemorrhagic cystitis** (Cottler-Fox et al, 1989). These conclusions have been confirmed by Drachenberg et al (1999).

The effects of human polyomavirus activation may be observed occasionally in **endocervical cells in smears of pregnant women** (Coleman et al, 1980) and in **bronchial cells** (see Chap. 19) but for reasons unknown, the most important and common manifestations are observed in urothelial cells in urinary sediment.

Cytology

There are **two types of polyomavirus manifestations** in the urinary sediment:

- **A massive presence of infected cells**, observed mainly but not exclusively in children and young adults and in people of all ages with impaired immunity (see Fig. 22-16A). Ito et al (1998) attributed this type of infection to BK virus.
- **Occasional, rare urothelial cells** with viral cytopathic changes, observed mainly in patients with no immunologic impairment (Fig. 22-17A). Ito et al (1998) attributed this type of infection to JC virus.

Figure 22-17 Polyomavirus infection. *A.* An oil immersion image of an infected cell showing the very large homogeneous nuclear inclusions surrounded by a thick nuclear membrane. *B.* Oil immersion view of a pale nuclear inclusion. In the cytoplasm, a nonspecific eosinophilic inclusion may be noted. *C.* Bladder biopsy in a case of polyomavirus infection. Several of the superficial umbrella cells show large viral inclusions. *D.* A histogram of DNA values in human polyomavirus infection. The non-diploid pattern of DNA distribution is readily seen.

Figure 22-18 Electron micrograph of a cell in the human urinary sediment infected with human polyomavirus. The crystalline arrays of virus particles, measuring about 45 nm in diameter, are clearly shown.

Figure 22-19 Polyomavirus nephropathy in a patient with AIDS. *A.* Urinary sediment showing numerous cells with viral inclusions. *B.* Kidney biopsy showing distortion of the tubules, many of which contain epithelial cells with large viral inclusions. *C.* Immunostain with antibody to SV40 virus showing positive staining reaction in cells of tubular lining.

Regardless of viral type, two stages of the infection may be recognized in the urinary sediment and both are diagnostic of the disorder. These are the **inclusion stage** and the **postinclusion stage**.

Inclusion Stage

- **Classical basophilic inclusions:** The infected cells vary in size and many are markedly enlarged. In its classical presentation, the virus forms single, dense basophilic homogeneous intranuclear inclusions that blend with the thick nuclear membrane (see Figs. 22-16A,B, 22-17A, and 22-19A). A narrow, clear halo may sometimes be seen between the edge of the inclusion and the marginal rim of nuclear chromatin. In multinucleated umbrella cells, each nucleus may contain an inclusion (see Fig. 22-16B). Similar inclusions may be observed in the superficial layers of the urothelium in fortuitous bladder biopsies from an infected person (see Fig. 22-17C) and in cytologic preparations from progressive multifocal encephalopathy (Suhrland et al, 1987).
- **Pale inclusions:** In a proportion of infected cells, the nuclear inclusions become pale and transparent, forming a homogeneous clear space within the infected nucleus (see Figs. 22-16C and 22-17B). The pallor is usually best seen in the central portion of the inclusion and it is nicely contrasted with the rim of the thick nuclear membrane. It is assumed, but it has not been proven, that this appearance of the inclusions is caused by leaching of the virus. Nonetheless, the pale inclusions are fully diagnostic of polyomavirus infection, as shown by immunochemistry (see below).

Postinclusion Stage.

Presumably because of the leaching out of the virus particles, **the nuclei of the infected cells that lost their viral content acquire a new appearance that, in my judgment, is just as characteristic of this infection as the inclusions.** The **enlarged nuclei** have an “empty” appearance with a distinct network of chromatin filaments wherein scattered **chromocenters may be observed** (see Fig. 22-16D). This has been described as a “fishnet-stocking” pattern. Transition forms between the inclusion-bearing cells and the “empty” cells may be observed. The presence of residual viral particles in such cells has been confirmed by **immunocytochemistry with an antigen to SV40 virus, which shares the antigenic properties with polyomaviruses**, obtained through the courtesy of Dr. Kertie Shah, Johns Hopkins School of Public Health, Baltimore, MD.

The scanty **cytoplasm of these dying or dead cells often contains small, irregular nonspecific eosinophilic inclusions which are not viral in nature** (see below).

Differential Diagnosis of Polyomavirus Infection

Although the similarities between the **basophilic polyomavirus inclusions and cytomegalovirus (CMV) inclusions**

P.761

are slight (see Figs. 22-15 with 22-16), inasmuch as the **polyomavirus inclusions have no halo and are not accompanied by satellite inclusions**, nonetheless, sometimes the differentiation cannot be securely made. In these cases, **the identity of the virus can be established** by immunologic, virologic, or serologic methods. Molecular techniques such as PCR (Ito et al, 1998) and in situ hybridization techniques with specific viral probes are also available. Electron microscopy may prove decisive because the CMV particles are very large (about 150 nm in diameter) and encapsulated, as are all the particles of the herpesvirus family, and do not form crystalline arrays. De LasCasas observed two cases of **adenovirus**, with intranuclear inclusions similar to those in polyomavirus and diagnosed by electron microscopy.

Diagnostic Significance of Polyomavirus Infection

The principal significance of the urothelial cell changes caused by polyomavirus activation is in an **erroneous diagnosis of urothelial cancer**. The so-aply named **decoy cells** have been mistaken for cancer cells on many occasions and frequently resulted in a very extensive and unnecessary clinical work-up, which included biopsies of the bladder, and cost vast sums of money.

In AIDS patients with renal dysfunction and in renal transplant patients, a simple examination of the urinary sediment may lead to the diagnosis and treatment of interstitial nephritis (Fig. 22-19).

Unfortunately, **polyomavirus infection may also occur in patients with urothelial cancer, particularly if treated with cytotoxic drugs**. In these infrequent cases, the inclusion-bearing and the “empty” cells may appear side by side with cancer cells. As is discussed in Chapter 23, the characteristic features of urothelial **cancer cells do not include smooth, homogeneous appearance of the nucleus or the characteristic filamentous chromatin pattern of the empty nuclei**.

Human Papillomavirus (HPV)

Infection of the lower urinary tract with HPV occurs with fair frequency. Because the infection is

related to **condylomata acuminata** and possibly cancer of the urethra and bladder, the topic is discussed in Chapter 23. However, it may be noted that **koilocytes in the urinary sediment in women may occur as a consequence of a “pick-up” of cells from the genital tract**. In such cases, further investigation of the genital organs is suggested before the much more complex investigation of the urinary tract is undertaken.

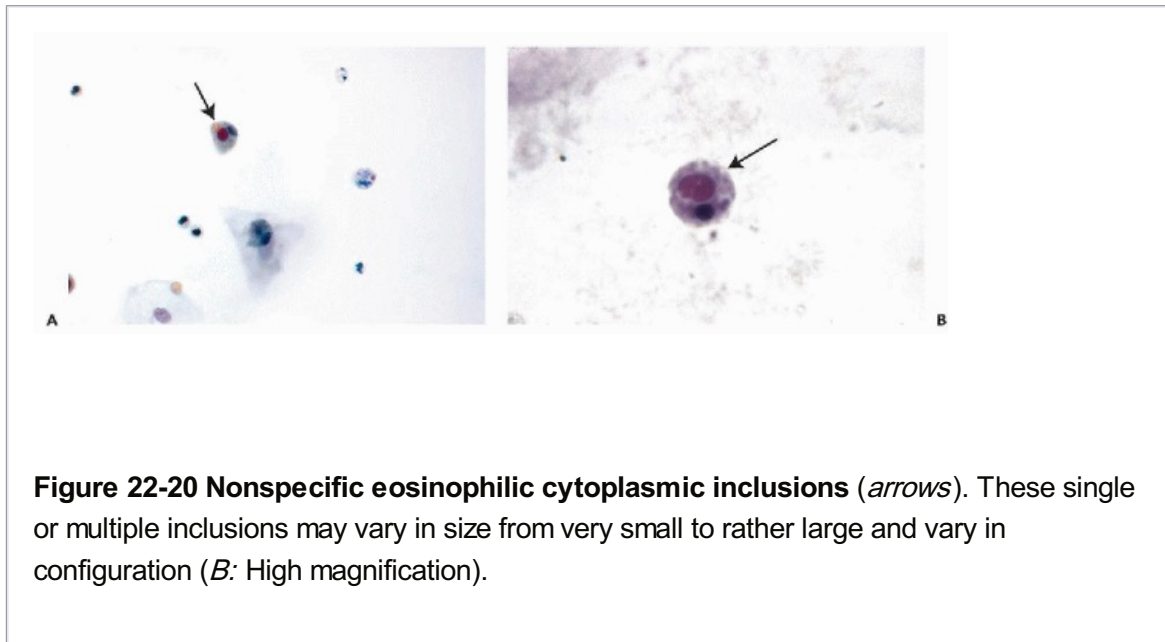

Figure 22-20 Nonspecific eosinophilic cytoplasmic inclusions (*arrows*). These single or multiple inclusions may vary in size from very small to rather large and vary in configuration (*B*: High magnification).

Cellular Inclusions in Urinary Sediment Not Caused by Viral Infection

Several types of cell inclusions that may be observed in the urinary sediment must be differentiated from viral inclusions.

Intracytoplasmic Eosinophilic Inclusions

On frequent occasions, **red, eosinophilic, opaque cytoplasmic inclusions, single or multiple**, may be noted within the benign or malignant epithelial cells in the urinary sediment. The inclusions vary in size and shape but most are **approximately spherical**, resembling droplets of red ink or red blood cells. Most of the inclusions appear in cells with a degenerated nucleus, as described for human polyomavirus infected cells. However, in some instances, the nucleus may still be well preserved (Figs. 22-20 and 23-15F). We have also observed **very large, homogeneous, eosinophilic cytoplasmic inclusions in poorly preserved urothelial cells** with vacuolated cytoplasm. Similar inclusions are frequently observed in degenerating intestinal **cells derived from ileal bladders** (see below). Dorfman and Monis (1964) documented that the inclusions contained mucopolysaccharides. Kobayashi et al (1984) reported a case of the rare **Kawasaki disease** with identical inclusions. Melamed and Wolinska (1961) studied these inclusions in a large number of cases. In this study, there was **no evidence of a specific association of the cytoplasmic inclusions with any known disease state**. Bolande's suggestion that these inclusions correlate with specific viral diseases of childhood was surely in error. Naib (personal communication) failed to identify any viral organisms in these inclusions and considers them as **products of cell degeneration**, possibly the result of prior viral infection. **Similar inclusions** may

P.762

be observed in degenerating cells of the respiratory tract in **ciliocytophthoria** (see Chap. 19) and occasionally in cells from other organs. Most patients with intracytoplasmic eosinophilic

inclusions in urinary sediment have some form of urinary tract disease or injury.

Inclusions Caused by Lead

Lead poisoning is not uncommonly observed in children and results in the formation of **intranuclear acid-fast inclusion bodies in renal tubular cells** (Fig. 22-21). Landing and Nakai (1959), who were the first to describe these inclusions, proposed that examination of the urinary sediment may lead to the correct diagnosis of the disease. This was confirmed by Schumann et al (1980) in industrial workers.

Eosinophilic Nuclear Inclusions

Such inclusions occurring in urinary sediment of women were described by Rouse et al (1986). Extensive investigations failed to uncover the nature of these inclusions. Electron microscopy was not performed.

Parasites

Trichomonas vaginalis

The parasite may be observed in the urinary sediment of both **female and male patients**. The presence of ***Trichomonas vaginalis*** in the male may be evident in urinary sediment **after prostatic massage** (for description of the parasite, see Chap. 10). A case of trichomonas infestation in a male patient with sterile pyuria was described by Niewiadomski et al (1998).

In female patients the parasites are usually of vaginal origin.

Schistosoma hematobium (Bilharzia) infestation

Infestation with the trematode or fluke ***S. hematobium*** is extremely widespread in certain parts of Africa, particularly along the Nile river (recent summary in Ross et al, 2002). The disease is transmitted from man to man through an intermediate host, a fresh-water snail. The mobile form of the parasite, the **cercariae**, penetrates the skin of people wading in the water, causing “**swimmers' itch**.” The cercariae travel to the veins of the pelvis, particularly the veins of the bladder, where they mature and copulate. The **ova, provided with a terminal spine** (see Figs. 10-35 and 23-27D), are deposited mainly in the submucosa of the distal ureter and the urinary bladder, although the rectum and the uterus may also be involved. The involvement of the **female genital tract** with this infestation is discussed in Chapter 10.

Figure 22-21 Lead poisoning. An intranuclear inclusion in an epithelial in urinary sediment (Hematoxylin-eosin; × 560. Courtesy of Dr. Benjamin Landing, Cincinnati, Ohio.)

The major importance of this infestation is its **frequent association with carcinoma of the bladder, mainly squamous carcinoma** (see Chap. 23). The reasons for this association are unclear; it may somehow be related to the severe inflammatory reaction and fibrosis of the bladder wall caused by the ova. **Keratin-forming squamous metaplasia of the urothelium is frequently observed and is thought to be a precursor of carcinoma.** The urinary sediment reflects such changes very closely: marked inflammatory epithelial changes, often associated with purulent exudate, are the rule in advanced schistosomiasis. In a study performed in our laboratories, numerous anucleated squames and squamous cells corresponding to squamous metaplasia were observed in 18 of 51 urine sediments from patients from Zimbabwe with schistosomiasis (Houston et al, 1966). Ova were not seen in this material. Somewhat similar observations were reported by Dimmette et al (1955).

Because of air travel and movement of infected people, the finding of *S. haematobium* is no longer confined to endemic areas. Clements and Oko (1983) reported such a case from New York City, and more such cases may be expected to occur in the Western world.

Filariasis

Filariasis, previously confined to endemic areas, may now be observed in other geographic settings. Webber and Eveland (1982) observed *Wuchereria bancrofti* filariae in urinary sediment of a patient in New York City. The presence of this worm is also discussed in reference to several other organs (see appropriate chapters).

URINARY CALCULI (LITHIASIS, STONES)

Urinary tract calculi (stones) cause **clinical symptoms** such as sudden onset of pain and hematuria. When the stones are located in the uretero-pelvic area, the pain is usually localized to the corresponding flank and may radiate to the

P.763

groin. Radiologic examination usually reveals a **space-occupying lesion. The differential diagnosis includes lithiasis, tumor, or a blood clot.** The urologist may resort to cytologic techniques to clarify the nature of the lesion. Cytologic investigation of the urinary sediment is rarely of help in solving the dilemma. Urinary calculi have two major effects on the urinary specimen:

- They may cause a significant **desquamation of urothelial cells because of their abrasive effect.** On a rare occasion, **smooth muscle cells**, presumably derived from the wall of the ureter, may be observed.
- They may cause **atypias of urothelial cells**, which are for the most part nonspecific.

Abrasive Effect in Voided Urine

A stone or stones, particularly when lodged in the renal pelvis or ureter, or when being actively expelled through the narrow lumen of the ureter, **may act like an abrasive instrument. Significant and sometimes massive exfoliation of urothelial cells, singly and in clusters**, may occur and may be observed in the urinary sediment (Fig. 22-22A). Among the

single cells, numerous large **multinucleated umbrella cells** are sometimes quite striking. Because of the customary variation in the sizes of the nuclei, such cells have been **mistaken for cancer cells** by inexperienced observers.

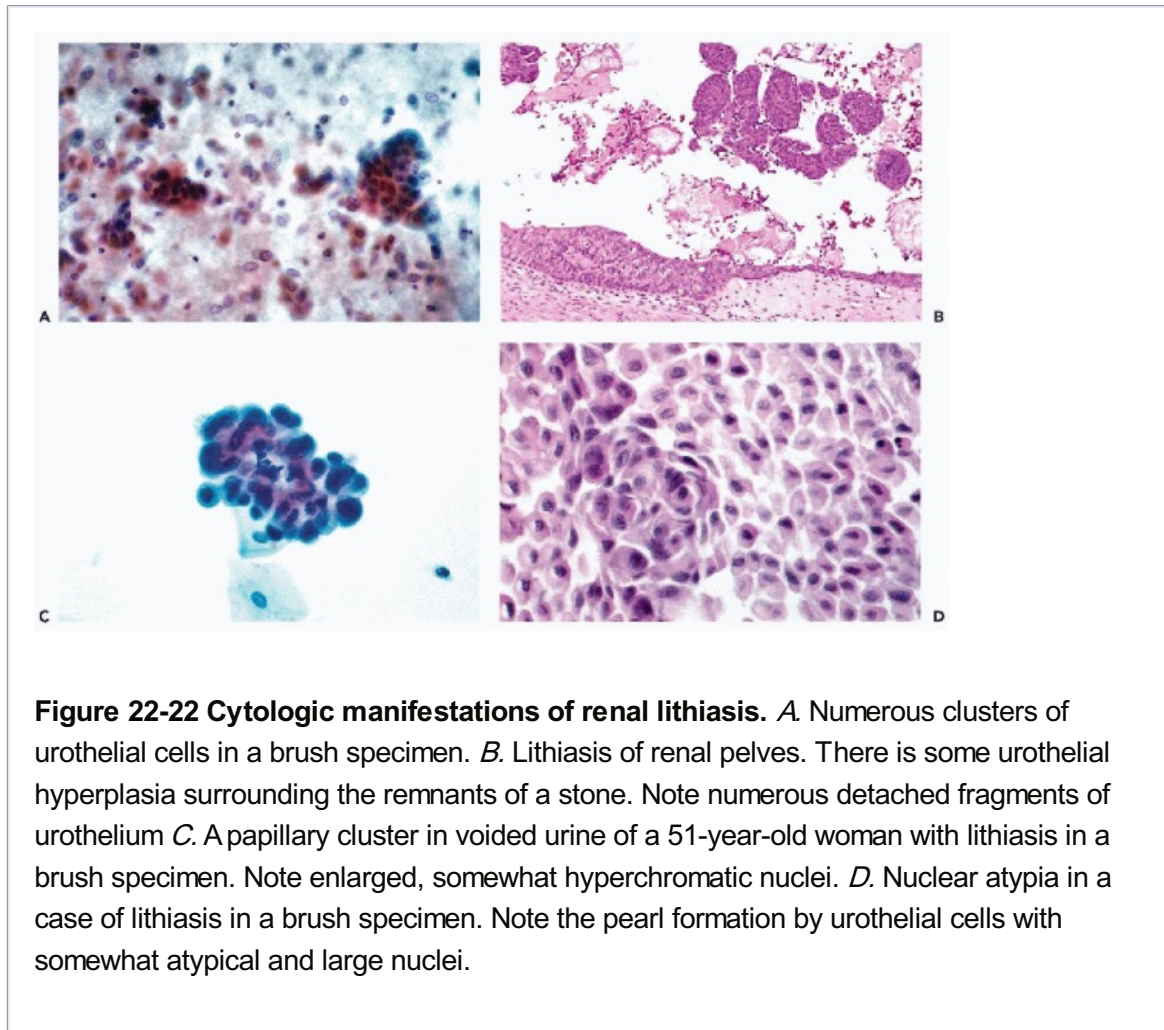

Figure 22-22 Cytologic manifestations of renal lithiasis. *A.* Numerous clusters of urothelial cells in a brush specimen. *B.* Lithiasis of renal pelvises. There is some urothelial hyperplasia surrounding the remnants of a stone. Note numerous detached fragments of urothelium. *C.* A papillary cluster in voided urine of a 51-year-old woman with lithiasis in a brush specimen. Note enlarged, somewhat hyperchromatic nuclei. *D.* Nuclear atypia in a case of lithiasis in a brush specimen. Note the pearl formation by urothelial cells with somewhat atypical and large nuclei.

More importantly, **cell clusters**, often numerous, may form **compact three-dimensional balls** or “**papillary**” clusters (Fig. 22-23A-C) that may be **mistaken for fragments of a papillary urothelial tumor**. Highman and Wilson (1982) observed papillary clusters of urothelial cells in voided urine in slightly more than 40% of 154 patients with calculi. They proposed that such clusters are predictive of calculi. They tested this hypothesis on more than 6,000 routine urine specimens and found similar clusters in 48 patients, of whom 30 were subsequently shown to harbor calculi. **In my experience, however, the presence of papillary clusters in voided urine is nonspecific, especially after palpation or catheterization of the bladder, and occurs in about 10% to 15% of all specimens from patients in whom no stones can be found.**

Stone-Induced Atypias of Urothelial Cells

In voided urine, urinary calculi may rarely cause alterations in the **shapes and sizes of urothelial cells**, sometimes with a **degree of nuclear hyperchromasia** that, in the absence

P.764

of any other nuclear changes, should be interpreted with caution (see Fig. 22-22D).

Crystalline deposits may be observed in the cytoplasm of such cells.

Figure 22-23 Leukoplakia in urinary sediment. *A.* Nucleated and anucleated squames in voided urine sediment. *B.* Biopsy of bladder wall showing a thick layer of keratin on the surface of the epithelium.

The Dutch investigator, Beyer-Boon (1977), has recorded 11 cases of lithiasis that resulted in sufficiently abnormal cytologic patterns to warrant the diagnosis of bladder cancer, occasionally of high grade. Highman and Wilson (1982) observed markedly atypical urothelial cells in 10 of 154 patients with calculi. In 1 of the patients, a major abnormality of the urothelium was observed on biopsy. None of the patients developed bladder cancer after a follow-up of 1 to 3 years. Personal experience does not support these views. In the past 30 years, I am aware of only 2 patients for whom a presumably erroneous diagnosis of urothelial cancer was made in the presence of lithiasis. One must keep in mind that **cancer of the urothelium and lithiasis may co-exist** and, in the presence of highly abnormal urothelial cells, cancer should be suspected (see Chap. 23). In fact, Wynder (1963), considered lithiasis as an important epidemiologic factor in bladder cancer. Hence, in the presence of **cytologic findings suggestive of cancer, further investigation of patients is necessary, whether or not there is associated lithiasis.**

Retrograde Sampling of Renal Pelves and Ureters in Lithiasis

It is not unusual for the urologist confronted with a space-occupying lesion of renal pelvis or ureter to resort to **retrograde catheterization or direct brushing** under the assumption that the cell sample will solve the diagnostic dilemma. Although these procedures are **sometimes useful in high-grade tumors** (see Chap. 23), they generally fail in distinguishing a stone from a low-grade papillary tumor.

Regardless of the medium of diagnosis, whether voided urine or samples obtained by instruments, the **differentiation of lithiasis from low-grade tumors cannot be accomplished by cytology** and must be based on clinical and radiologic data.

LEUKOPLAKIA OF BLADDER EPITHELIUM

Chronic inflammatory processes in the urinary bladder often associated with **lithiasis**, or in Africa with **schistosomiasis**, may result in the formation of **squamous metaplasia**, which may occur anywhere in the bladder or the renal pelvis and should be differentiated from the squamous epithelium often observed in the trigone of the normal female. Squamous epithelium with a **thick layer of keratin on the surface** appears white on cystoscopy and is known as **leukoplakia** (Fig. 22-23B). **Keratinizing squamous cancer of the bladder may develop**

from this disorder (see Chap. 23).

Cytology

Leukoplakia of the bladder sheds mature squamous cells and anucleated squames that are found in the urinary sediment. The **anucleated squames have a yellow cytoplasm in Papanicolaou stain** (Fig. 22-23A). The diagnostic significance of such findings varies. In **voided urine** from either a female or a male patient, the presence of mature nucleated squamous cells is of **no diagnostic value**. If a **catheterized specimen contains anucleated squames, the presence of leukoplakia in the urinary tract is probable and cystoscopy should be recommended**. Leukoplakia of the lower urinary tract must be considered a potentially dangerous lesion that may be associated with squamous carcinoma with which it may share similar cytologic presentation (see Chap. 23).

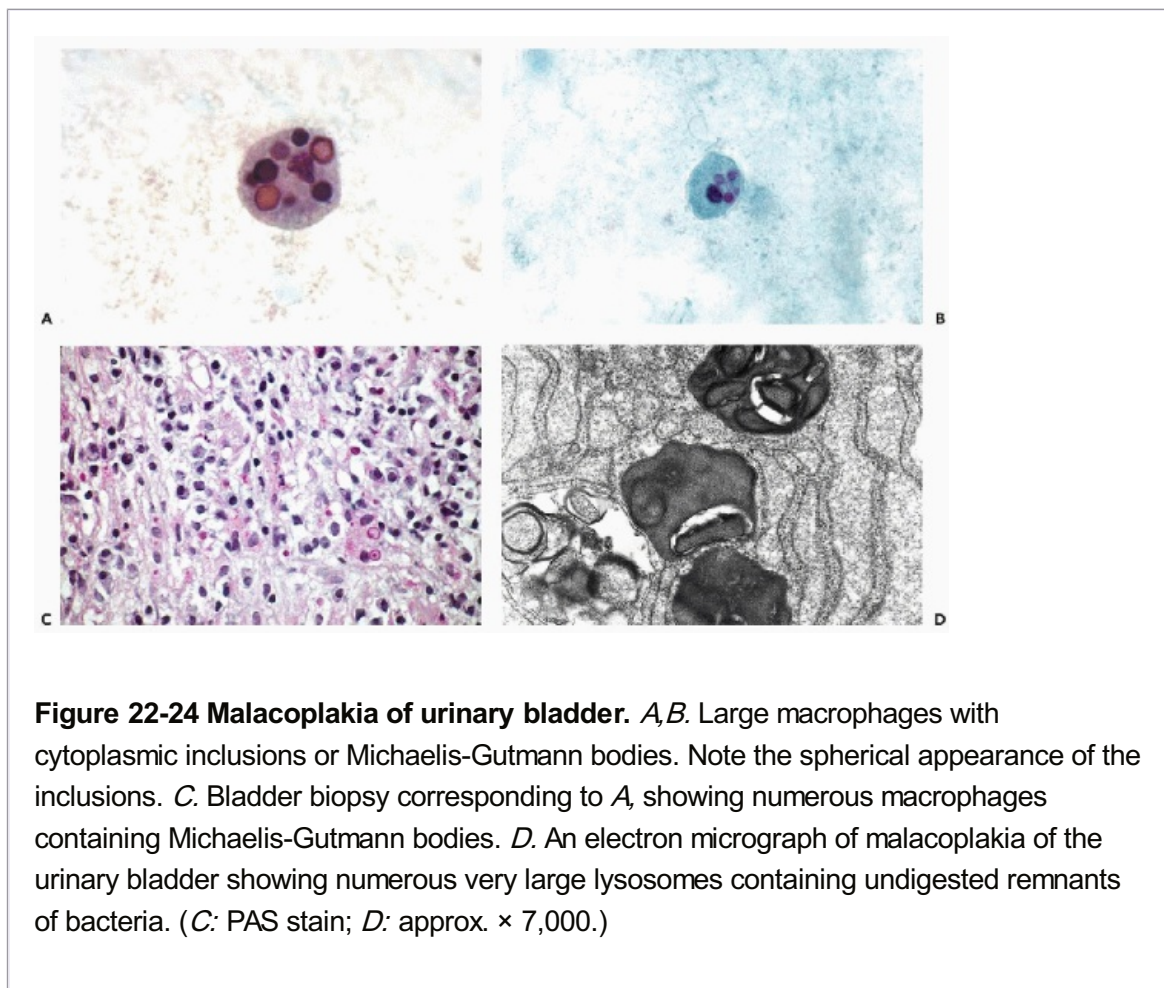

MALACOPLAKIA OF BLADDER

Clinical Data and Histology

Malacoplakia (from Greek: *malako* = soft and *plax* = plaque) is a rare disorder first described in the urinary bladder and subsequently observed in many other organs, such

P.765

as the bronchus (see Chap. 19). The bladder lesion is characterized grossly by formation of **yellow soft plaques involving the urothelium and bladder wall**.

The lesions are located in the lamina propria and are separated from the lumen of the bladder

by normal urothelium. The lesions are composed of **sheets of large, polygonal mononucleated macrophages**. The cytoplasm of these cells contains **spheroid, laminated, sometimes calcified concretions (Michaelis-Gutmann bodies)** (Fig. 22-24C). It has been shown that malacoplakia represents an **enzymatic deficiency of macrophages** that are unable to digest bacteria, are usually coliform. Electron microscopy has shown that the **Michaelis-Gutmann bodies represent giant cytoplasmic lysosomes containing phagocytosed bacteria that later become calcified in a concentric fashion and may contain iron** (Fig. 22-24D).

Cytology

Because malacoplakia is a subepithelial process, it is generally not accessible to cytologic sampling. However, if the epithelium is damaged, for example after a biopsy, the characteristic cytologic features of the disease may be recognized in the urinary sediment. In a case reported by Melamed (1962) and in other cases subsequently observed by us and others, **numerous cells in the urinary sediment of patients with malacoplakia contained one or more spherical Michaelis-Gutmann bodies. Concentric calcific laminations were readily identifiable in some, but not all, of the bodies** (Fig. 22-24A,B). Although urothelial cells may occasionally contain specks of calcium in the presence of lithiasis, the Michaelis-Gutmann bodies have a sufficiently unique appearance to be considered diagnostic of malacoplakia.

URINE OBTAINED THROUGH AN ILEAL BLADDER

An ileal bladder or ileal conduit is a container constructed surgically from a segment of small bowel to function as a substitute bladder, usually after cystectomy for cancer (Bricker, 1950). The ureters are transplanted and open into the lumen of the ileal bladder, which is usually anchored to the abdominal wall. The urine from the conduit is collected in a container. Another artificial bladder is the **Indiana pouch** built from cecum, ascending colon and the ileum that allows the patient to have some control of voiding (Rowland et al, 1987). For reasons that are discussed in detail in Chapter 23, cytologic follow-up of patients treated for bladder cancer is of considerable importance and requires

P.766

familiarity with the make-up of the urinary sediment derived from the ileal conduit.

Cytology

Urinary sediments obtained from an ileal bladder are always **rich in small epithelial cells of small bowel origin**, which occur singly and in large clusters. **Rarely, the original columnar configuration of such cells is well preserved**. Typically, these **cells are spherical, oval, or somewhat irregular**, resembling macrophages (Fig. 22-25A). Their **cytoplasm is often frayed and may show vacuolization** and the **spherical nuclei, although of monotonous size, may appear hyperchromatic**. Most of these cells are very poorly preserved and show **nuclear pyknosis and apoptosis (karyorrhexis)** and **numerous nonspecific eosinophilic cytoplasmic inclusions** (Fig. 22-25B-D). There is no known clinical significance to these findings, which are present in most patients with an ileal bladder. The ileal bladder cells must be differentiated from cancer cells, derived from the ileal bladder, ureter, or renal pelvis, described in Chapter 23. Watari et al (2000) studied the urinary sediment on patients with Indiana pouch and failed to observe any intestinal-type cells.

Figure 22-25 Cells derived from ileal bladders. The dominant cell in normal ileal bladder urine is a rounded, macrophage-like epithelial cell, undoubtedly derived from the intestinal lining. In Figures A, C, and D, scattered columnar intestinal epithelial cells may be observed. Note that the cytoplasm of most cells is degenerated and that many of them contain the nonspecific eosinophilic cytoplasmic inclusions or show nuclear disintegration. (B: High magnification).

CYTOLOGIC CHANGES CAUSED BY THERAPY

Urinary Sediment After Surgical Procedures

Urine samples, obtained shortly after transurethral resection of the prostate or other surgical procedures, usually show marked **acute inflammatory changes, sometimes with an admixture of eosinophils. Electrocautery**, used for biopsies, may cause **homogeneous nuclear enlargement and pyknosis in urothelial cells**, occasionally mimicking nuclear changes observed in bladder cancer. These changes may persist for 2 or even 3 weeks following the procedure. Errors in interpretation are avoided by knowledge of clinical history and cytologic follow-up 4 to 6 weeks after the surgical procedure. Fanning et al (1993) described a **spindly artifact** of urothelial cells after laser treatment caused by coagulation of epithelial surface. These authors cautioned against misinterpretation of such changes.

Epithelial regeneration that follows a biopsy or a surgical procedure may also result in some **atypia of urothelial cells and mitotic activity** that may be observed in urinary sediment. The **nuclei of the urothelial cells may show some granularity and sometimes contain visible nucleoli** and may show mitotic activity (Fig. 22-26A). As a rule,

P.767

these changes do not last more than **2 to 3 weeks after the procedure**. If significant cell abnormalities persist beyond that period, the possibility of a residual or recurrent malignant tumor cannot be ruled out.

Figure 22-26 Effect of treatment on urothelial cells. *A.* Bladder brush a few days after transurethral resection for prostatic hypertrophy. Note the cluster of deeper urothelial cells, some showing mitotic activity (*arrow*). *B-D.* Effects of radiotherapy. *B.* A markedly distorted large urothelial cell after 35 GY. *C.* Same case as *B.* Note the large cytoplasmic vacuole. *D.* Radiation effect in a 20-year-old man with retroperitoneal Hodgkin's disease. The enlargement of the urothelial cell and nuclear break-down are shown.

Radiotherapy

Irradiation of the pelvic organs produces marked changes in the urinary bladder. Edema of the bladder wall is usually marked and there are also changes in blood vessels and the stroma. The **epithelial cells** share the fate of irradiated cells in other organs (see Chaps. 18 and 19) and **become enlarged**. The cytoplasm becomes **vacuolated and at times eosinophilic**. Their **nuclei** are also **enlarged**, occasionally showing **vacuolization, pyknosis and apoptosis (karyorrhexis)** (Fig. 22-26B-D). The value of cytologic assessment of radiotherapy for primary carcinoma of the bladder is discussed in Chapter 23.

Radiation changes in the **bladder** following **radiation treatment of carcinoma of the cervix** have resulted in serious diagnostic problems. Evaluating the **presence or absence of metastatic carcinoma of the cervix within the bladder** on the basis of the urinary sediment is at times **difficult** and, on at least one occasion, it was erroneous because irradiated urothelial cells were mistaken for cells of epidermoid carcinoma. As elsewhere in similar situations, it appears wise to **withhold diagnostic judgment in the presence of radiation changes** until clear-cut evidence of cancer has been obtained.

Chemotherapy

Certain alkylating drugs, particularly **cyclophosphamide**, administered as an **immunosuppressive and therapeutic agent**, exercise a marked effect on the epithelium of the urinary bladder.

Cyclophosphamide

Cyclophosphamide (Cytoxan, Endoxan) is related to nitrogen mustard but is, per se, inactive

until metabolized in the liver. In patients, the products of metabolism of the drug are rapidly excreted in the urine and have a marked cytotoxic effect, causing **hemorrhagic cystitis** that may lead to intractable hemorrhage necessitating surgical treatment (Berkson et al, 1973). This effect of cyclophosphamide may be attenuated or eliminated by hydration of the patient and by certain drugs.

Experimental evidence (Koss, 1967) supports the view

P.768

that metabolites of cyclophosphamide exercise a direct and marked effect on the epithelium of the bladder: in the rat, a single intraperitoneal injection of the drug in the dose of 200 or 400 mg/kg produced **rapid necrosis of the bladder epithelium, followed by marked atypical hyperplasia**. Cells from the hyperplastic epithelium showed **marked atypia, comparable to abnormalities observed in human material**. It has also been shown experimentally that by diverting the urine from the bladder, the drug effect could be prevented (Bellin et al, 1974).

Cyclophosphamide-induced abnormalities are not confined to the epithelium. There is experimental evidence that **subepithelial blood vessels and smooth muscle of the bladder may be severely damaged** (Bonikos and Koss, 1974). It has also been recorded that in children, fibrosis of the bladder wall may occur after exposure to this potent drug (Johnson and Meadows, 1971).

Effects on Urothelial Cells

The cytologic changes in patients receiving cyclophosphamide for a variety of malignant diseases were first described by Forni et al (1964). The changes observed were somewhat similar to those following radiation treatment. The most striking feature was **marked but variable cell enlargement, usually pertaining to both the nucleus and the cytoplasm**. The study of patients from the very beginning of treatment suggested that the **nuclear enlargement preceded cytoplasmic abnormalities**. The **enlarged nucleus was often eccentric, slightly irregular in outline, and nearly always markedly hyperchromatic**. The **chromatin granules** were at times **coarse** but their distribution was usually fairly even, giving the nucleus a “**salt-and-pepper**” appearance (Fig. 22-27). A **chromocenter or a nucleolus or two** were often well in evidence and **sometimes very large**. The large nucleoli were frequently distorted, with irregular and sharp edges. In **female patients, the sex chromatin body was often visibly enlarged**. Occasionally, multinucleated cells were noted with some variability in the sizes of the component nuclei. **Nuclear pyknosis and apoptosis (karyorrhexis)** were common **late effects**, resulting in large and hyperchromatic nuclei. The **cytoplasm** commonly showed **marked vacuolization** and sometimes contained particles of foreign material or was infiltrated by polymorphonuclear leukocytes. Occasionally, bizarre cell forms were observed. In some instances, the cytologic changes due to cyclophosphamide therapy may be extremely severe and **imitate urothelial carcinoma to perfection**. In cases showing such marked cell changes as those just described, the **smear**

P.769

background often contained numerous erythrocytes, cellular debris, and leukocytes.

Figure 22-27 Effect of cyclophosphamide on urinary bladder epithelium. *A.* Smear pattern in voided urine showing numerous cells with large hyperchromatic nuclei. *B.* Similar nuclear abnormalities in a patient treated for large cell lymphoma. *C.* Nuclear enlargement and hyperchromasia in a patient treated for leukemia. *D.* Biopsy of bladder in the same patient as *C*, showing nuclear enlargement in the epithelium surmounting a hemorrhagic stroma, the latter is characteristic of cyclophosphamide effect.

It must be noted that there was no direct correlation between the degree of cytologic atypia and the dosage of the drug, as shown by Forni et al (1964). Histologic changes in biopsies of the bladder show very marked epithelial abnormalities which, at the height of the cyclophosphamide effect, are akin to carcinoma in situ (Fig. 22-27D), but can regress after cessation of therapy. It has been shown by Jayalakshamma and Pinkel (1976) that **simultaneous radiotherapy enhances the effects of cyclophosphamide** on the bladder.

The cytologic changes caused by cyclophosphamide should **not be confused with synchronous urothelial cell abnormalities due to human polyomavirus activation**, which are quite common in such patients and were described above. The drug has an immunosuppressive effect and, thus, it may contribute to reactivation of the virus. As discussed above, there is no evidence that the polyomavirus activation has any bearing on the occurrence of **hemorrhagic cystitis** in patients with bone marrow transplants (Cottler-Fox et al, 1989). In fact, it is likely that the hemorrhagic cystitis may have been caused in these patients by cyclophosphamide.

The most significant complication of cyclophosphamide therapy has been the occurrence of cancer of the lower urinary tract, recorded in several patients **after longterm administration of large doses of the drug** for unrelated malignant disease, usually a lymphoma, but sometimes for a benign disorder (Schiff et al, 1982). **Bladder carcinomas** were reported by Worth (1971), Dale and Smith (1974), and by Wall and Clausen (1975). A squamous carcinoma of the bladder was personally observed in a 19-year-old girl with a history of 24 months of cyclophosphamide therapy (Fig. 22-28A) and an adenocarcinoma in a 77-year-old woman who received the drug for many years for Waldenstrom's macroglobulinemia (Siddiqui et al, 1996). **Carcinomas of the renal pelvis** (Fuchs et al, 1981,

McDougall et al, 1981) and of **the ureter** (Schiff et al, 1982) were also recorded under similar circumstances. Several cases of **leiomyosarcoma of the bladder** have been observed, usually several years after completion of treatment for a malignant lymphoma with large doses of cyclophosphamide (Rowland and Eble, 1983; Seo et al, 1985; Kawamura et al, 1993). Thrasher et al (1990) described a leiomyosarcoma of bladder after treatment for lupus nephritis. An example of a leiomyosarcoma of the bladder after cyclophosphamide therapy is shown in Figure 22-28B, courtesy of Dr. Lawrence Roth of Indianapolis, Indiana. Sigal et al (1991) described a **synchronous leiomyosarcoma and an invasive carcinoma** in a patient treated for lymphoma. An **excess of bladder cancer** was observed in patients treated with cyclophosphamide for **Hodgkin's disease** (Pedersen-Bjergaard, 1988) and **non-Hodgkin's lymphomas** (Travis et al, 1989). Although in some of the older patients, the bladder cancer may have been an incidental, new primary tumor, some of the observed patients were sufficiently young to suggest that the drug acted as a carcinogenic agent. This possibility is not unique to cyclophosphamide, and it has also been suggested for other alkylating agents (see Chap. 18). These observations strongly suggest that clinical and cytologic follow-up of patients receiving cyclophosphamide therapy is prudent. In patients in whom cell abnormalities develop and persist during and after cyclophosphamide therapy, clinical investigation of the bladder is warranted.

Figure 22-28 Malignant tumors in patients treated with cyclophosphamide. A. Urothelial carcinoma in a 47-year-old male with multiple myeloma. **B.** Leiomyosarcoma of bladder in a 17-year-old man treated for malignant lymphoma. (*B*: Courtesy of Dr. Lawrence Roth, Indianapolis, IN.)

Busulfan

The marked effects of busulfan (Myeleran) on the epithelia of the cervix and the lung were described in Chapters 18 and 19. It is not surprising, therefore, that the drug also has a marked effect on the epithelium of the urinary tract. **Large cells with atypical large nuclei may be observed in renal tubules and the epithelium of the renal pelvises. The urinary bladder** may even show **abnormalities resembling carcinoma in situ**. The **urinary sediment** of patients receiving busulfan may contain **abnormal epithelial cells**, difficult to differentiate from cancer cells. Examples of cell abnormalities caused by busulfan are shown in Chapter 18. The role of busulfan as a possible carcinogenic agent is extensively

P.770

discussed in Chapter 19, to which the reader is referred for further information.

Intravesical Drug Therapy

A number of drugs such as **triethylenethiophosphoramide (Thiotepa)**, **doxorubicin hydrochloride (Adriamycin)**, and **mitomycin**, are being used intravesically for treatment of some bladder cancers, mainly carcinoma in situ, and for prevention of recurrences of papillary tumors. In my experience, **urothelial cell changes observed with these drugs are relatively trivial and consist of a radiomimetic effect** (cell and nuclear enlargement). I have not seen any drug-induced nuclear abnormalities that mimic carcinoma (except for an **occasional polyomavirus activation**). Thus, **the presence of identifiable cancer cells in the urinary sediment during the monitoring of such patients usually indicates a lack of tumor response to treatment**. In experimental dogs treated with intravesical doxorubicin and Thiotepa, similar observations were recorded: cell and nuclear enlargement, multinucleation, and karyorrhexis were the principal transient abnormalities noted (Rasmussen et al, 1980).

Immunotherapy with *Bacillus Calmette-Guérin* (BCG)

Immunotherapy with the attenuated *Mycobacterium bovis* strain, bacillus Calmette-Guérin (BCG) is now extensively used for treatment of flat carcinoma in situ of the bladder. The **monitoring of these patients by cytologic examinations of urinary sediment** is mandatory and the results are described in Chapter 23. The agent may produce **tuberclelike granulomas in the bladder wall, indistinguishable from tuberculosis**. In a fortuitous case, **clusters of epithelioid cells, forming a granuloma, may be observed in the urinary sediment** (Fig. 22-29). For further discussion of effects of treatment on bladder cancer, see Chapter 23.

Figure 22-29 Granulomas in voided urine sediment of a patient treated with BCG for carcinoma cite A & B in situ of the bladder. Both photographs show plump epithelioid cells in a tight cluster. No giant cells were observed in this case; *B*: high power. (Case courtesy of Dr. Ruth Kreitzer, Mount Sinai Hospital, New York, NY.)

Aspirin and Phenacetin

Prescott (1964) pointed out that the nephrotoxic effect of these drugs may be assessed in urinary sediment by performing **counts of renal tubular cells**. This is best accomplished by staining the sediment by the method described by Prescott and Brodie (see Chap. 44), which stains leukocytes deep blue, renal tubular cells pink, and erythrocytes red. This method was used by Prescott to demonstrate a marked increase in the desquamation of renal tubular cells

in patients receiving aspirin, phenacetin, and related drugs. The significance of these drugs in the causation of carcinoma of the renal pelvis is discussed in Chapter 23.

URINARY SEDIMENT IN ORGAN TRANSPLANTATION

One of the greatest medical advances of our era has been the ability to substitute a diseased organ of a patient with a transplanted organ (allograft) obtained either from a living or deceased donor. Although knowledge of human immunology has made great strides and much more is known about the mechanisms of tissue matching and prevention of rejection than a few years ago, nevertheless, in spite of effective therapy, the rejection of the transplanted organ by the recipient remains a serious risk in every case. It is beyond the scope of this work to discuss all the manifestations of organ rejection. Only some of the effects on the urinary sediment will be discussed here in reference to bone marrow and renal transplantation.

Bone Marrow Transplantation

The procedure is used in **patients with treatment-resistant leukemias and lymphomas and in the treatment of some solid tumors and some patients with nonmalignant blood disorders** (summary in Stella et al, 1987). The preparation of the patients for a transplant involves **ablation of**

P.771

the marrow by total body irradiation and large doses of drugs, such as cyclophosphamide and busulfan (summary in Cottler-Fox et al, 1989). Perhaps the most common event in the bone marrow transplant patients is the **activation of polyomavirus infection, with resulting nuclear inclusions**, described and illustrated above.

Both radiation and drugs may affect the urothelial cells when applied singly, as discussed above. The combination of these procedures may be very difficult to interpret. As an example, the urinary sediment and bladder biopsies in a 43-year-old man with bone marrow transplant for leukemia are shown in Figure 22-30. The **urinary sediment** showed **radiomimetic effect** but also contained **bizarre malignant-looking cells with huge, hyperchromatic nuclei**. The **biopsy** of the bladder showed epithelial changes **mimicking urothelial carcinoma in situ**. The patient died and similar abnormalities were found in the epithelium of the bladder at postmortem examination. Because of multiple modes of treatment in this case, no single cause of the epithelial abnormalities can be ascertained. It is important, however, to recognize that cyclophosphamide may be the cause of bladder cancer (see above). In an excellent study, Stella et al (1992) compared change caused by conditioning therapy in bone marrow transplant recipients with cells harvested in urinary sediment from patients with bladder cancer. Although significant differences were observed in patients with low-grade tumors, the separation of therapy-induced changes from cells of high-grade carcinomas was very difficult.

Figure 22-30 Urine sediment in a 45-year-old male treated with a bone marrow transplant for malignant lymphoma. *A* Shows markedly enlarged urothelial cells, consistent with radiation effect. *B, C* Show a variety of abnormal cells with large homogeneous nuclei next to urothelial cells of normal size and configuration. *D* Shows a bladder biopsy with remarkable nuclear abnormalities in the epithelium consistent with a carcinoma in situ. (Case courtesy of Dr. Denise Hidvegi, Northwestern University, Chicago, IL.)

Changes caused by radiotherapy and by cyclophosphamide may also occur simultaneously (Fig. 22-30A). Cell changes mimicking (or perhaps representing) cancer may be observed. On the other hand, it is known that organ transplant patients are prone to develop various forms of cancer, including carcinomas and malignant lymphomas (see discussion of this topic in Chap. 18). Hence, it remains a possibility that carcinomas in situ of the urinary bladder may occur in transplant patients.

Renal Transplantation

Renal transplantation in patients in uremia caused by renal failure is the oldest and one of the most successful procedures of its kind. Following the transplantation, the patients are immunosuppressed by a variety of drugs. The greatest danger to these patients is transplant rejection, which may be prevented by adjusting the dosage of the immunosuppressing agents.

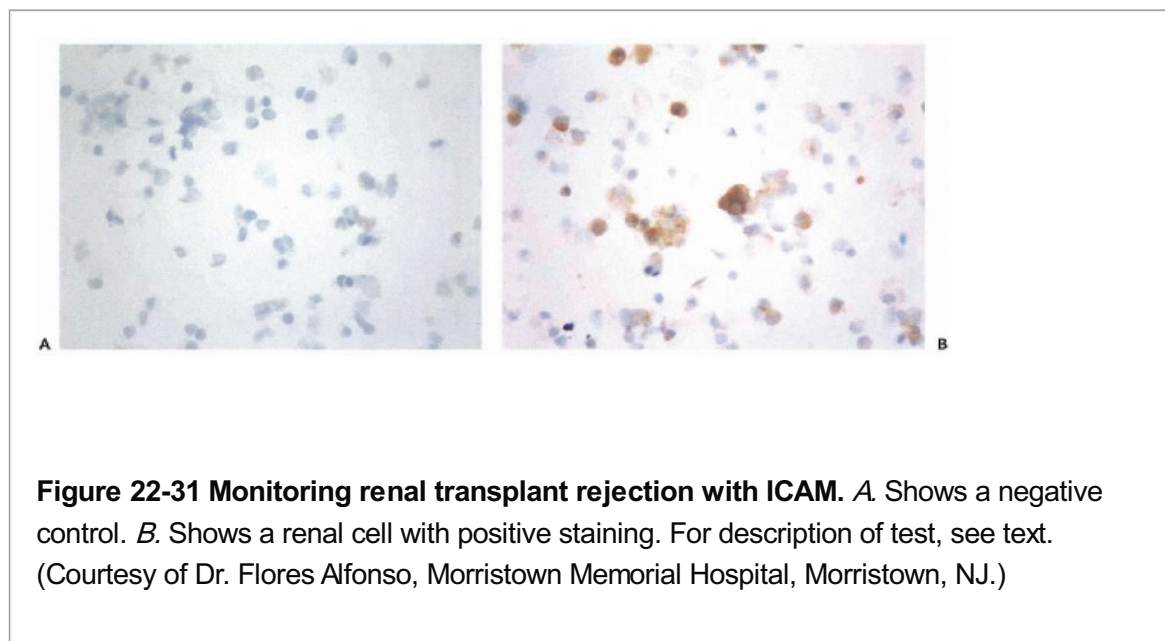

P.772

Monitoring of renal rejection by urinary sediment analysis was proposed in the late 1960s. Bossen et al (1970) studied a profile of urinary sediment that was composed of seven features observed before and during episodes of renal allograft rejection. These features were:

- Necrotic material forming the background of smears (“dirty background”)
- Nuclear degeneration
- Tubular casts
- Erythrocytes

- Mixed cell clusters (epithelial and leukocytes)
- Lymphocytes
- Tubular cells

At least five of these features were observed in every patient prior to episodes of rejection. The **two most constant features were the presence of lymphocytes and of tubular cells**. The mere increase in cellularity of the smears was a hint of impending rejection. In the absence of rejection, the urinary sediment had low cellularity and a clean background. If the rejection episode was controlled by therapy, there was an improvement in the profile of features discussed above. Bossen et al recommend an evaluation of the **urinary sediment profile** for monitoring renal transplants **as more reliable than any single feature**, such as the presence of lymphocytes or tubular cells, as previously advocated by Kauffman et al (1964) and by Taft and Flax (1966). Schumann et al (1977) advocated use of the cytocentrifuge for the study of urinary sediment and confirmed that the presence of tubular cells, singly or in casts, was of great prognostic value of impending rejection (see Figs. 22-11D and 22-12). In a subsequent communication, Schumann et al (1981) discussed at length the criteria for **recognition of renal fragments and tubular cells** in the urinary sediment. These authors stressed the close relationship of tubular cells with casts and the cylindric fragments corresponding to tubular cells. With the use of Bales' method of urine fixation and processing, the recognition of casts in the sediment is significantly enhanced.

Spencer and Anderson (1979) stressed that numerous **viruses**, such as **cytomegalovirus**, **herpesvirus (including herpes zoster)**, and **human papillomavirus** may become activated in the immunosuppressed renal allograft recipients. These authors reported that the infection with **cytomegalovirus was particularly serious**. **Human polyomavirus activation**, easily detected in voided urine, is also of major prognostic significance as narrated above (Drachenberg et al, 1999).

Since the publication of these early papers, considerable progress has been made in the **recognition of molecules that participate in organ rejection** (summary in Corey et al, 1997b). In a series of elaborate studies on serial urine samples in ten pediatric patients, processed by the method of Bales (see Chap. 44), these authors compared the predictive value

of urine cytology with renal biopsies (Corey et al, 1997a) and conventional cytology with immunostaining for **receptors of adhesion molecules ICAM-1 and interferon gamma and TNF- α receptors**, two molecules that regulate the expression of ICAM-1 (Corey et al, 1997b). In conventional cytology, **organ rejection was anticipated when the urine sample contained less than 55% neutrophils and more than 20% lymphocytes**. The reading of the cytology specimens was more reproducible than the reading of biopsies. In immunostudy of nonrejecting patients, the tubular cells expressed only the interferon gamma receptor. In the graft-rejecting patients, the tubular cells expressed ICAM-1 and TNF α receptors but not the interferon gamma receptor (Fig. 22-31). This study, in which each step was carefully controlled and each morphologic observation was confirmed by two observers, opened new possibilities in monitoring renal transplant patients.

Aspiration Biopsy

Häyry and von Willebrand (1981a) used percutaneous fine-needle aspiration technique (FNA) for monitoring of renal transplants. The technique, described in detail by the same authors (1981b, 1984), samples the cortical area of the graft. **Three types of cells are evaluated in smears** stained with

P.773

May-Grünwald-Giemsa (MGG): the **large distal tubular cells**, either granulated or nongranulated, **small proximal tubular cells**, often forming clumps, and **endothelial cells**. The viability of these cells was evaluated on a scale from one to four, one indicating normal cells and four necrotic cells. The **extent of inflammation in the smear** was based on a **differential count** of leukocytes, **compared with the differential count in a simultaneously obtained sample of peripheral blood**. The results were compared with biopsy material and found to be accurate. Several **types of leukocytes** were recognized and classified in these samples. **Lymphocytes and monocytes** were the first inflammatory cells seen in the transplant. The appearance of **blast cells indicated that the function of the transplant deteriorated**. Granulocytes did not appear in the samples until late in rejection. **Platelets** were also studied with specific antibodies and have been shown to be **increased during rejection episodes**. Still, the finding of a **large number of tissue macrophages was the most secure evidence of acute transplant rejection**. Häyry, in a summary paper (1989), discusses the clinical value of the FNA technique and several ancillary laboratory procedures, as a most accurate method of monitoring renal transplants, leading to appropriate adjustments in antirejection therapy and salvage of allografts. The technique has been successfully used by Bishop et al (1989). It requires a dedicated team and a specialized laboratory for successful execution and has not achieved widespread acceptance.

Cyclosporine Effect

Cyclosporine is an immunomodulatory drug extensively used in organ transplant recipients to prevent rejection. The drug affects renal function in about 30% of the patients. Winkelmann et al (1985) and Stella et al (1987) described **necrosis of renal tubular epithelial cells** and the presence of **"tissue fragments" in the urine of bone marrow transplant patients** as evidence of cyclosporine toxicity. Similar conclusions were reached by Stilmont et al (1987). So far as one could judge from the photographs, the changes were not specific. Most unfortunately, many people knowledgeable about organ transplants who write about the cytologic findings in the urinary sediment are not familiar with the scope of urinary cytology. A number of published articles confuse common findings with transplant-specific findings. As an

example, a paper by Stella et al (1992) shows cells with typical polyomavirus inclusions as evidence of “urothelial toxicity” following bone marrow transplantation. **The reader should be skeptical of much of the published work on this subject written by people with limited experience in urinary cytology.**

Because the allograft recipients routinely receive immunosuppressive drugs, they are subject to infections by agents that are uncommonly observed in nonsuppressed patients. These are mainly viral agents, which have been discussed in detail above. Such patients also run a substantial risk of developing malignant tumors, such as malignant lymphomas or other cancers, as discussed in Chapter 18.

Tumors of the Urinary Tract in Urine and Brushings*

TUMORS OF THE UROTHELIUM (TRANSITIONAL EPITHELIUM) OF THE BLADDER

Epidemiology

In the United States, tumors of the bladder are the **fourth leading type of cancer in men** but are less common in women (Messing and Catalona, 1998). During the second half of the 20th century, a statistically significant increase in the rate of urothelial tumors, mainly tumors of the urinary bladder, has been observed in most industrialized countries

P.778

(Cole et al, 1971, 1972; Wynder et al, 1977; Silverman et al, 1992). For the year 2001, the American Cancer Society projected more than 54,000 new cases and 12,400 deaths from tumors of the bladder (Greenlee et al, 2001).

The impact of **environmental factors** on the genesis of tumors of the bladder has been known since the publications by the German surgeon Rehn (1895 and 1896), who observed that workers in factories producing **aniline dyes** were at a high risk for this disease. It was subsequently shown that the carcinogenic compounds to which these workers were exposed were **aromatic amines**, such as 2-naphthylamine, para-aminodiphenyl (xenylamine), and 4-4'-diaminobiphenyl (benzidine) (Bonser et al, 1952; Boyland et al, 1954). Another compound known as MBOCA [4,4' methylenobis (2-chloroaniline)], an analogue of benzidine, has been shown to induce low-grade papillary tumors in the bladder (Ward et al, 1988). The drug **chlornaphazine**, related to the aromatic compounds, was shown to be carcinogenic for the bladder (Videbaek, 1964; Laursen, 1970). The effects of the alkylating agent **cyclophosphamide** as a carcinogen in the lower urinary tract were extensively discussed in Chapter 22. Women working in factories producing **phenacetin**, a common analgesic, and heavy users of the drug are also at increased risk for urothelial tumors that may involve the bladder but also the ureters and the renal pelves (Johansson et al, 1974; Mihatsch, 1979; Lomax-Smith, 1980; Piper et al, 1985). There also is evidence that workers in **rubber and cable, leather, and shoe repair industries** are at a high risk for bladder cancer, although the specific carcinogenic substances have not been clearly identified. Nortier et al (2000) reported that the use of a **Chinese herb (*aristolochia fangchi*)** may also be a risk for bladder tumors. Along similar lines, bladder tumors in cattle have been linked with consumption of another plant, bracken fern (***pteris aquilina***) (Pamukcu et al, 1964; Hirono et al, 1972). Experimental data suggested that bladder tumors in cattle fed bracken fern may also be associated with **bovine papillomavirus type 2** (Campo et al, 1992). A high level of **inorganic arsenic** in drinking water is another cause of bladder cancer (Cohen et al, 2000; Steinmaus, et al, 2000). Bladder

cancer is by far the most common tumor in the population at risk, although organs such as the lungs may also be affected. Bladder tumors observed in Taiwan in areas of high arsenic concentration, are commonly associated with arteriosclerotic changes in lower extremities known as the “black foot” disease (Chiang et al, 1993; Chiou et al, 1995, 2001). The association has also been observed in Chile (Smith et al, 1998) and Argentina (Hopenhayn et al, 1996). The mechanisms of arsenic carcinogenicity are unknown (Simeonova and Luster, 2000).

Besides the environmental factors, there are other risk factors for tumors of the bladder. For example, **paraplegic and quadriplegic patients** are at risk, presumably because of inadequate voiding, and therefore exposure of the bladder to small doses of unknown carcinogenic agents contained in the urine (Kaufman et al, 1977; Bejany et al, 1987; Bickel et al, 1991). **Similar mechanisms may be responsible for bladder tumors in** otherwise normal men with **low intake of fluids** (Michaud et al, 1999) and enlargement of the prostate.

Work from this laboratory has shown that **prostatic enlargement, whether caused by hyperplasia or carcinoma, is another risk factor for cancer of the bladder**. Between January 1974 and August 1977, we observed 19 patients, seen primarily because of prostatic enlargement, whose urinary sediment disclosed an **occult urothelial carcinoma**, subsequently confirmed by biopsies of bladder. Further review of the files at Montefiore Medical Center, compiled by Dr. Allayne Kahan, disclosed 13 patients with coexisting carcinomas of the prostate and of the bladder and an additional 28 patients with benign prostatic hypertrophy and bladder cancer (unpublished data). Barlebo and Sørensen (1972) observed 2 patients with carcinoma in situ of the bladder, initially seen because of prostatic hypertrophy. A further association of bladder cancer with prostatic disease was reported by Mahadevia et al (1986), also from this laboratory. Mapping of 20 cystoprostatectomy specimens removed because of invasive high-grade bladder cancers or carcinoma in situ, or both, disclosed that occult carcinoma of the prostate was present in 14 of the 20 patients, **but only one of these lesions was suspected before cystectomy. These observations strongly suggest that in all patients with prostatic enlargement, whether benign or malignant, bladder cancer should be ruled out**. In fact, Nickel et al (2002) reported that three urothelial carcinomas in situ were observed among 150 patients with chronic prostatitis evaluated by urine cytology. Conversely, male patients with known tumors of the bladder should be investigated for coexisting prostatitic carcinoma. The urologists are generally unaware of this association.

Tumors of the bladder are observed with high frequency in some geographic areas. In the United States, these tumors are often observed in the state of New Jersey and in New Orleans, presumably because of a high level of exposure to **industrial waste**. In Egypt and many other African countries, an infection with the parasite ***Schistosoma haematobium (Bilharzia)*** is an important cause of bladder cancer, as discussed in Chapter 22 and in this chapter. Still, many patients with bladder tumors have no known risk factors. It is speculated that industrial pollution, cigarette smoking, or a combination of these and other yet unknown factors contribute to cancers of the lower urinary tract.

Terminology

The **unique features of the epithelium lining the lower urinary tract** were discussed at length in Chapter 22 and need not be repeated here. Many of these features, such as the **presence of the asymmetric unit membrane and umbrella cells**, are observed in tumors derived from this epithelium. Further, the presence of **uroplakins, proteins uniquely**

characterizing this epithelium (summaries in Wu et al, 1994 and Sun et al, 1999), have been shown to be an important diagnostic and experimental tool, as discussed elsewhere in this chapter. For all these reasons, the term **urothelial tumors or carcinomas** has been used in the previous additions of this book and in other writing, replacing the old term **transitional cell tumors or**

P.779

carcinomas (Koss, 1974, 1985, 1995). The term **urothelial tumors** has now been accepted by consensus of urologic pathologists (Epstein et al, 1998).

Classification and Natural History

The accomplishments and limitations of cytology in the diagnosis and follow-up of tumors of the bladder can only be understood against a background of histologic and clinical observations. It is of interest that cytologic observations on urinary sediment played a key role in establishing the current concepts of classification and natural history of these neoplasms (summary in Koss, 1995).

TABLE 23-1 CHARACTERISTICS OF TWO GROUPS OF UROTHELIAL TUMORS		
Feature	Low-Grade Papillary Tumors	High-Grade Papillary Tumors and Invasive Carcinomas
Epithelial abnormality of origin	Hyperplasia	Flat carcinoma in situ and related abnormalities: atypical hyperplasia (or dysplasia)
Invasive potential	Low	High

Recognition in urine cytology	Poor	Good to outstanding, depending on grade and DNA ploidy
DNA ploidy pattern	Predominantly diploid	Predominantly aneuploid
Density of nuclear pores	Normal	Increased
Expression of Ca antigen (epitectin)	As in normal urothelium	Increased
Blood group isoantigen expression	Usually present	Usually absent
Mutation of p53 gene	Usually absent	Usually present

Two Pathways of Bladder Tumors

For many years, most urothelial tumors of the bladder, the ureter, and the renal pelvis were thought to be malignant and were classified as “carcinomas,” regardless of their morphology. Within the last half a century, evidence has been provided that there are significant differences in the behavior and prognosis among these tumors based on **their morphology and clinical presentation** (Fig. 23-1 and Table 23-1).

P.780

The urothelial tumors of the bladder may be classified into **two fundamental, although to some extent overlapping, groups with different patterns of behavior, different prognoses and different cytologic presentation. These are:**

- **Papillary tumors**
- **Nonpapillary tumors**

The papillary tumors of the urothelium have for the most part, a different natural history from the nonpapillary, flat tumors. It is of particular importance to recognize that many common, well-differentiated papillary tumors (low-grade tumors) should not be classified as “carcinomas” because they do not, or very rarely, progress to invasive cancer. On the other hand, **nonpapillary or flat urothelial lesions (carcinoma in situ and related abnormalities) are the principal precursor lesions of invasive urothelial cancer.** It is only recently that the community of urologic pathologists incorporated some of these concepts into the classification of tumors of the urothelium (Epstein et al, 1998), even though they have been advocated for many years in previous editions of this book and other writings (Koss, 1975, 1985, 1995).

Although this simple classification of urothelial tumors is based primarily on their morphologic characteristics, it is also supported by differences in **biologic and behavioral features** that

will be briefly mentioned here and are discussed in detail below.

There are significant **differences in DNA content** among the different categories of urothelial tumors with **all, or nearly all, low-grade papillary tumors having a DNA content in the normal range (diploid) and all, or nearly all, high-grade lesions, whether papillary or nonpapillary, having an abnormal DNA content (aneuploid)**. Several studies support further the concept of two pathways of bladder tumors. Thus, a study of the **density distribution of nuclear pores** (see Fig. 2-22 for description) was shown to correlate with DNA ploidy. The number and density of nuclear pores was significantly higher in aneuploid than in diploid tumors (Czerniak et al, 1984). The **expression of a monoclonal antibody Ca1 (epitectine)**, a presumed marker of surfaces of cancer cells (Ashall et al, 1982), was also shown to be higher in all but one of 12 aneuploid tumors when compared with diploid tumors and normal urothelium (Czerniak and Koss, 1985). Molecular biology of these tumors is discussed further on in this chapter.

Very strong support for the concept of two pathways of bladder tumors has been recently offered based on experimental evidence in transgenic mice. Uroplakin II gene promoter was used to introduce two different oncogenes into the ova. **The mice bearing the Ha-ras oncogene developed superficial, noninvasive papillary tumors**, whereas mice bearing the **T antigen of the SV40 virus developed flat carcinomas in situ and invasive bladder cancers** (Zhang et al, 1999, 2001). Recent molecular studies of fibroblast growth factor receptors (FGFR3), expressed in low-grade tumors, and p53 overexpression in high-grade tumors, also confirmed the concept of two pathways of bladder carcinogenesis (van Rhijn et al, 2004). It must be noted that in several recent studies, **genetic abnormalities were observed in morphologically normal urothelium adjacent to tumors** (Czerniak et al, 1995, 1999, 2000; Cianciulli et al, 2003).

Papillary Urothelial Tumors

Fundamental Structure and Clinical Presentation

Papillary urothelial tumors are **by far, the most common form of urothelial tumors** seen in the practice of urology. They occur in all age groups, even in children and adolescents, although they are more common in older patients. When first observed, they may be **single or multiple**. The **fundamental structure** of all papillary tumors is the same. The tumors form a **fern-like, cauliflower, or sea anemone-like protrusion** into the lumen of the organ, be it urinary bladder, renal pelvis, or the ureter. The papillary tumors may have a narrow base and a **single stalk** or may be **sessile, that is, having a broader base with multiple, branching stalks**. Each stalk is composed of a **central core of connective tissue and vessels, supporting epithelial folds of varying degrees of thickness and cytologic abnormality** (Fig. 23-2A,B). The make-up of the epithelium is used to classify these tumors further (see below).

It has been proposed, based on molecular analysis (Sidransky et al, 1991; Steiner et al, 1997) and comparative genomic hybridization (Simon et al, 2001), that multifocal papillary tumors of the bladder are of **monoclonal origin, that is, the result of proliferation of a single cell**. This theory assumes that multiple or recurrent tumors are the result of **intraepithelial migration of cells of the same clone**. In spite of molecular evidence, this **theory cannot be sustained**. There is no evidence whatever that urothelial cells, bound to each other by desmosomes, would undertake a perilous journey across long distances to settle in a different

portion of the bladder epithelium and produce another papillary tumor. It is more likely that identical molecular abnormalities may affect cells in various segments of the bladder at different times as a result of a “**field change**” induced by carcinogens. For further discussion of molecular biology of urothelial tumors, see below.

Symptoms

The thin and delicate branches of the papillary tumor break easily, leading to the principal symptom of papillary tumors, **hematuria**. The bleeding is often intermittent, with episodes of hematuria occurring sporadically at the time of voiding. Hematuria may be significant, resulting in grossly bloody urine, or it may be relatively minor, resulting in microhematuria (for discussion of the significance of microhematuria, see Chap. 22). Hematuria may be associated with other symptoms such as dysuria and frequency of urination.

Precursor Lesions: Urothelial Hyperplasia

Papillary tumors are derived from **thickened urothelium, composed of more than the normal seven layers of cells**

P.781

without nuclear abnormalities, a condition known as hyperplasia. The thickness of the urothelium may be quite **variable, ranging from a slight increase to 20 layers of cells or more.** The hyperplastic epithelium is well differentiated and its surface is usually formed by umbrella cells (Fig. 23-2C). **There are two morphologically identical types of hyperplasia:**

Figure 23-2 Papillary tumors of bladder. *A* A typical papillary tumor with thin branches carrying capillary vessels. *B* Sessile papillary tumor in whole bladder mount. *C* Hyperplasia of urothelium. Note the increased number of epithelial layers and absence of nuclear abnormalities. *D* Incipient papillary tumor. The presence of a capillary vessel within the hyperplastic epithelium is the cardinal event. (*B*: Case courtesy of Dr. Rolf Schade, Birmingham, UK.)

- Reactive hyperplasia
- Neoplastic hyperplasia

Reactive hyperplasia may occur in **inflammatory or reactive processes** or as a consequence of an **underlying space-occupying lesion**. Neoplastic hyperplasia may be the **source of well-differentiated, low-grade papillary tumors** and was shown in experimental systems by Koss and Lavin (1971), Koss (1977) and more recently in transgenic mice by Zhang et al (2001). **Because the two types of hyperplasia cannot be distinguished from each other morphologically**, the diagnosis depends on the environment in which this change occurs. **Neoplastic hyperplasia** often contains **branches of submucosal vessels** that provide the blood supply and stalk of the growing tumor (Fig. 23-2D). This **interplay between mucosal thickening and vascular proliferation is an essential sequence of events in papillary tumors**. There are no molecular-biologic data explaining this phenomenon, but it may be speculated that a **combination of angiogenesis and a defect in the epithelial adhesion molecules must combine to form these tumors**. Taylor et al (1996) also considered urothelial hyperplasia as a precursor lesion of papillary tumors. **Urothelial hyperplasia cannot be identified cytologically**.

Histologic Grading of Papillary Tumors

In 1922, Broders, of the Mayo Clinic, observed that the behavior of papillary tumors of the bladder depended significantly on the **morphologic make-up of their epithelium and introduced the concept of tumor grading**. The current prevailing system of histologic grading is summarized

P.782

in Table 23-2 (Koss, 1975, 1995, Epstein et al, 1998). **The grading is based on the degree of epithelial abnormality**.

TABLE 23-2 CLASSIFICATION AND GRADING OF PAPILLARY TUMORS OF THE BLADDER*				
	Number of Epithelial Cell Layers	Superficial Cells	Nuclear Enlargement	Abnormalities Hyperchromasia
Papilloma	No more than 7	Present, albeit small	Not significant	Absent
Papillary tumors grade I (papillary neoplasm of low malignant potential)	More than 7	Usually present, albeit small	Slight to moderate	Slight in occasional cell
Papillary carcinoma	More than	Variable	Moderate to	Slight to

grade II (papillary carcinoma, low grade)	7, usually marked increase		marked	moderate in 25-50% of cells
Papillary carcinoma grade III	More than 7, often marked increase	Usually absent	Marked; extreme variability of sizes	Marked in 50% or more of cells

* Note: In practice, it may prove difficult to fit any given case into this classification. Intermediate classifications such as I-II or II-III have been used. For all intents and purposes, a separation of tumors grade III from tumors grade IV is not warranted biologically and both groups can be considered as one.

Modified from Koss LG. Tumors of the Urinary Bladder. Atlas of Tumor Pathology, 2nd series, Fascicle 11. Washington, D.C., Armed Forces Institute of Pathology, 1975, WHO recommended terminology (1998).

Low-Grade Tumors

Papillomas and low-grade papillary tumors (papillary tumors of low malignant potential or grade I papillary tumors) share in common an **orderly epithelium** of variable thickness that shows **either no deviation or only minor deviation from normal urothelium**. The **size of the cells increases toward the surface, which is usually composed of umbrella cells** (Fig. 23-3A,B). The difference between these two entities are relatively trivial: in **papillomas**, the **thickness of the epithelium is within the normal seven-layer limit and there are no nuclear abnormalities**. In the **papillary tumors of “low malignant potential,”** the **epithelial lining is somewhat thicker and less orderly, but umbrella cells are usually present on the surface. Although most nuclei are within normal limits, occasional enlarged and hyperchromatic nuclei may be present, particularly in grade I tumors**. Mitoses are infrequent.

Because of rarity of progression to invasive cancer, the term “carcinoma” should not be used in reference to this group of papillary tumors. Pich et al (2001) reported that papillary tumors of low malignant potential have a lower proliferation rate, lower expression of p53, and lower recurrence rate than tumors classified as low-grade papillary carcinomas. These differences are not reflected in the morphology of these tumors.

Papillary tumors may contain mucus-producing goblet cells in their lining. Papillomas of squamoid type may contain squamous “pearls” (see below).

High-Grade Tumors (Grades II and III)

Papillary tumors of higher grades show **significant cytologic abnormalities of the epithelial lining. Many of these tumors are broad-based or sessile** and are lined by an **epithelium that is usually composed of an increased number of layers of medium-sized cells that are arranged in a less orderly fashion and show a limited tendency to surface maturation (formation of umbrella cells) than the urothelium of low-grade tumors** (Fig.

23-3C). Such tumors always show nuclear abnormalities in the form of hyperchromasia, variability in nuclear sizes, and mitotic activity. These tumors are usually referred to as *papillary carcinomas*, subdivided into grades II and III.

Papillary carcinomas of high grade (grade III) are characterized by an epithelium composed of highly abnormal cells of variable sizes with major nuclear abnormalities, readily recognized as cancer cells. Mitoses, often abnormal, are frequently observed (Fig. 23-3D). In some of these tumors, the make-up of the epithelium may be identical to flat carcinomas in situ, described below.

The common **papillary carcinomas grade II** are intermediate between the tumors grade I and tumors grade III. Although **retaining the fundamental structure of the urothelium, they show varying degrees of epithelial maturation and nuclear abnormalities that may be distributed throughout the epithelium or limited to patchy areas.**

In practice, it is not unusual to observe tumors with a mixture of patterns side by side. Thus, combined grades of classification may have to be used, such as **grade I-II, II-III, etc.**, often combined with a descriptive comment. The problems of precise grading and, accordingly, behavior and prognosis of papillary tumors, particularly of the intermediate grade II, have led to several methods of objective analysis. There is evidence that the **grade II tumors may be separated into two prognostic groups according to their DNA content**, which may be within **normal or diploid range, or abnormal (aneuploid)**, a feature that may play a major role in clinical behavior and cytologic recognition of these tumors (see below).

P.783

Figure 23-3 Papillary tumors of bladder, various grades. *A.* Papilloma, low power view. The somewhat thickened epithelium shows no nuclear abnormalities whatever. *B.* Papillary tumor, grade I (tumor of low malignant potential). The epithelium, although orderly, shows slight nuclear enlargement. *C.* Papillary carcinoma, grade II. The surface epithelium of this tumor shows significant nuclear enlargement, hyperchromasia, and mitotic activity. *D.* Papillary tumor, grade III or IV. The epithelium lining the tumor is composed of cancerous cells.

Papillary Tumors and Pseudoinvasion of Bladder Wall

Many papillary tumors, regardless of grade, may **have roots extending into the lamina propria** of the urothelium in the form of broad-based bands of cells in continuity with surface of urothelium. In my judgment and experience, **this extension should not be considered as evidence of invasion**, so long as there is **no splintering** of the tumor tissue into individual cells (Fig. 23-4).

Behavior Patterns

Papillary tumors when first seen by a urologist are either **single or multiple** and are **usually noninvasive** (i.e., they are confined to the urothelium or, at most, extending to the lamina propria) and therefore can be treated by simple excision. The **term “non-invasive papillary tumor” is much more accurate than the term “superficial bladder tumors,”** which has been extensively used and abused in the literature. For further discussion of this issue, see below “tumor staging.”

Recurrence or New Tumors

After surgical removal of the primary papillary tumors, new such tumors may be observed in **the same or other areas of the bladder** and much less often, in **the ureters or the renal pelves**. The term, **recurrence**, which is in common use to describe these events, is **inaccurate**, inasmuch as the original tumors, if carefully removed, do not recur. The **new tumors** may be single or multiple and may be identical to the original tumor or show greater degree of epithelial abnormality (see Fig. 23-5). **The probability of “recurrence”** varies with the grade of the tumor: **low-grade tumors, such as papillomas or grade I tumors, are less likely to be followed by new tumors than are tumors of grade II or III**. Recurrent tumors are much more common in older patients than in children or adolescents. **Abnormal expression of cytokeratin, 20 (CK20)**, normally confined to the superficial cell layers, was proposed **as a marker for recurrence of papillary tumors** (Harnden et al, 1995). However, Alsheikh et al (2001) found that the **CK20 staining differences** between the recurrent and nonrecurrent low-grade papillary tumors were **statistically not significant**.

Progression of Bladder Tumors to Invasive Cancer

The progression rate of urothelial papillomas to invasive cancer is extremely low.

Cheng et al (1999C) confirmed this observation on 52 patients with a very long-term follow-up.

P.784

The progression rate of the papillary tumors grade I (tumors of low malignant potential) is of the order of 3% or less. Cheng et al (1999D) observed only four invasive carcinomas in a group of 112 patients with long-term follow up, although 29 patients had recurrent noninvasive papillary tumors. Similar observations were reported by McKenney et al (2003). In our experience, the invasive tumors in such patients are usually derived from occult carcinomas in situ (see below). Richter et al (1997) reported genetic differences between noninvasive and superficially invasive grade I tumors. These observations are of theoretical interest only and are discussed below.

Figure 23-4 A. Schematic representation of pattern of invasion of papillary tumors. On the left, the roots of the tumor are located in the lamina propria. The roots have smooth borders and do not indicate invasion. On the right, the pattern of true invasion shows spike-like extensions of the tumor into the lamina propria. B. An illustration of an early invasion of the lamina propria of the bladder.

The behavior of grade II papillary carcinomas depends on their DNA ploidy: papillary carcinomas grade II with a diploid DNA content have a similar behavior pattern to grade I papillary tumors. High-grade papillary tumors, including carcinomas grade II, mainly those with abnormal (aneuploid) DNA content, and all carcinomas grade III, progress to invasive carcinoma in a substantial proportion of cases, probably not less than 25%. Invasive carcinoma may develop directly from sessile higher-grade papillary tumors, but it more commonly develops from adjacent areas of cystoscopically invisible urothelial abnormality, such as carcinoma in situ and related lesions (see Fig. 23-1 and comments below on the derivation of invasive cancer of the bladder). In fact, the prognosis of papillary tumors depends not only on the grade of the tumor but also on the level of histologic abnormality of the flat urothelium peripheral to the visible lesion (intraepithelial urothelial neoplasia), discussed below. It must be stressed that the most invasive and metastatic bladder cancers are not derived from papillary lesions but from flat carcinoma in situ and related lesions, discussed below.

Figure 23-5 Multiple recurrent low-grade papillary tumors in a whole bladder mount. Case courtesy of Dr. Rolf Schade, Birmingham, UK.

Nonpapillary Urothelial Tumors

Nonpapillary urothelial tumors occur in **two forms: invasive carcinoma and its precursor lesions, and flat carcinoma in situ and related abnormalities (intraurothelial neoplasia, or IUN).**

Invasive Urothelial Carcinomas

Clinical Presentation and Natural History

Most invasive cancers of the bladder are discovered “**de novo**” in patients seen because of hematuria, frequency, and other common nonspecific symptoms referable to a dysfunction of the bladder. On cystoscopy, either a protruding or an ulcerated lesion is observed. It has now been documented that in about **80% of the cases, primary invasive carcinomas of the bladder are *not* preceded by papillary tumors** (Brawn, 1982; Kaye and Lange, 1982); hence, the conclusion is that **most invasive bladder cancers are derived from cystoscopically invisible and usually asymptomatic flat lesions, namely carcinoma in situ and related abnormalities, discussed below.** In approximately 20% of cases of invasive carcinoma preceded by papillary tumors,

P.785

it has been documented, by **mapping the urinary bladders,** that invasive cancer is usually **derived not from the papillary tumors but from adjacent epithelial segments showing carcinoma in situ or related lesions** (Koss et al, 1974, 1977; Koss, 1979) (Fig. 23-6).

Figure 23-6 Mapping of urinary bladder, removed surgically because of a very large papillary tumor with extension into the lamina propria. Three peripheral foci of invasion are surrounded by carcinoma in situ and related abnormalities (dysplasia).

Figure 23-7 Patterns of invasive cancer of the urinary bladder. *A.* Urothelial carcinoma, grade II. The pattern mimics a papillary tumor. *B.* Urothelial carcinoma, grade III. The tumor is composed of sheets of poorly differentiated cancer cells. *C.* Squamous carcinoma with a pseudosarcomatous reaction. The presence of cancer cells in the loosely structured part of the tumor was documented by keratin staining. *D.* Leather bottle bladder showing the presence of signet ring cancer cells in the wall of the bladder. (*D*: Mucicarmine staining.)

Histologic Patterns

Urothelial carcinomas may show a **broad variety of histologic patterns** ranging from **urothelial carcinomas, solid or mimicking papillary tumors, to tumors composed of spindle and giant cells, mimicking sarcomas, to highly anaplastic large- and small-cell cancers, the latter akin to oat cell carcinoma** (Fig. 23-7A,B). Other variants of bladder cancer, such as **squamous carcinomas and adenocarcinomas**, may either occur as a **focal change in urothelial tumors or as a primary tumor type** (Fig. 23-7C,D). These variants may be recognized in cytologic material and will be discussed separately. Mahadevia et al (1989) pointed out that primary and metastatic bladder tumors may induce a **pseudosarcomatous stromal reaction**, mimicking a spindle-cell carcinoma or a sarcoma (Fig. 23-7C). Other rare variants of urothelial cancer are discussed below.

P.786

Grading

Invasive carcinomas of the bladder composed of orderly sheets of cells resembling normal urothelium (grade I tumors) are very rare. Virtually all invasive tumors are **grade II, III, or sometimes IV**, depending on the **level of architectural and cytologic abnormality**. **Grade II tumors** mimic papillary tumors of higher grades and are composed of sheets of relatively uniform cancer cells separated from each other by bands of connective tissue. **Grade III tumors** are usually solid and are characterized by variability in the size of cancer cells and marked nuclear abnormalities. **Grade IV tumors** are either composed of large cancer cells, spindle and giant cells, or of small cancer cells (small-cell carcinomas).

Staging

Assuming competent treatment, the prognosis of invasive cancer of the bladder depends mainly on the stage of the disease at discovery and the presence or absence of metastases. The diagram in Figure 23-8 shows the principles of staging of bladder tumors. The staging is also applicable to tumors of the renal pelvis and ureters, although in these organs, therapeutic options are more limited. **Tumors with invasion limited to the lamina propria (Stage T_{1A}) fare better than tumors with invasion of the principal bladder muscle (muscularis propria). In the assessment of invasion, the muscularis propria should not be confused with the thin and incomplete layer of muscle observed in some patients in the lamina propria (muscularis mucosae).** In practice, tumors invading the main bladder muscle to various depth (stages T₃ and T₄) have a poor prognosis and do not respond well to therapy, although there are some exceptions to this rule.

Figure 23-8 Modified clinical staging of bladder cancer according to the TNM system (top line). It was recognized that there are two types of noninvasive tumors: flat carcinoma in situ (TIS) and papillary tumors (Ta). The two entities have unequal prognosis inasmuch as most invasive cancers (T₂ and T₃) are derived from TIS (see text). N indicates lymph node metastases to pelvic nodes (N₂) and aortic nodes (N₄). The prognosis of invasive tumors depends on stage.

The left side of the diagram in Figure 23-8 pertains to **noninvasive tumors**. After many years, the staging system finally recognized the **major behavioral and prognostic differences between noninvasive papillary tumors, now designated as T_a, and flat carcinoma in situ, now designated as T_{IS}**. Still, even today (in 2004), many urologists (and some pathologists) speak of “**superficial carcinomas**,” without recognizing the major prognostic differences between the two entities. The difference is particularly significant from the cytologic point of view, as will be set forth below.

Precursor Lesions of Invasive Urothelial Carcinoma (IUN)

By far, the most important precursor lesion of invasive urothelial carcinoma is **flat carcinoma in situ** (Schade and Swinney, 1968). **However**, there are **lesser degrees of urothelial abnormalities** (urothelial atypia, dysplasia) that have been shown to be **precursor lesions of invasive urothelial tumors**. It was proposed (Koss et al, 1985; Koss, 1995) that **all these flat lesions, including carcinoma in situ, may be conveniently included under the term intraurothelial neoplasia (IUN), and subject to grading** in a manner similar to precancerous epithelial abnormalities of the uterine cervix (CIN) (see Chap. 12). The **term has been accepted as an alternate to carcinoma in situ and dysplasia in the new WHO nomenclature** (Epstein et al, 1998; Cina et al, 2001). Three grades of abnormality of the urothelium may be distinguished:

P.787

- **Atypical urothelium (mild dysplasia) or atypical urothelial hyperplasia (IUN I or low-grade IUN)**
- **Markedly atypical urothelium (moderate or severe dysplasia) (IUN-II)**
- **Flat carcinoma in situ (IUN-III)**

- IUN II and III can be combined as high-grade IUN.

Flat Carcinoma In Situ (IUN III)

Carcinoma in situ of the bladder was first described as “**Bowen's disease**” of bladder **epithelium** by Melicow and Hollowell (1952) as a microscopic abnormality of bladder epithelium, accompanying visible papillary tumors (Fig. 23-9). For several years, the significance of the lesion was not recognized until a major follow-up study of workers exposed to a potent carcinogen, *p*-aminodiphenyl (Melamed et al, 1960; Koss et al, 1965; Koss et al, 1969). This study documented that **clinically occult primary carcinoma in situ, identified in the sediment of voided urine because of the presence of cancer cells, is the principal precursor lesion of invasive cancer**, as confirmed by subsequent studies on the origins of primary invasive cancer of the bladder (Brawn, 1982; Kay and Lange, 1982).

Two forms of carcinoma in situ can be identified:

- **A primary form**, occurring as the initial lesion
- **A secondary form**, accompanying papillary lesions of the bladder (see Figs. 23-9).

Clinical Presentation

Carcinoma in situ of the bladder may be **completely asymptomatic** or may cause **nonspecific symptoms** commonly associated with cystitis or prostatic disease. Carcinoma in situ of the urinary bladder **cannot be recognized as a tumor on cystoscopic examination**. The most common visible alteration is **redness of the epithelial surface, sometimes described as “velvety redness,”** caused by inflammatory changes and vascular dilatation in the underlying stroma (Fig. 23-10). Other changes may mimic inflammation, **cobblestone mucosa, interstitial cystitis**, etc. However, **many carcinomas in situ do not form any visible abnormalities at all**. The **diagnosis** of the lesion **depends**, therefore, on **either recognition of cancer cells in the urinary sediment or a fortuitous biopsy of the urothelium**.

Figure 23-9 Cross-section of human bladder (A) with two types of tumors side-by-side:

a papillary tumor (small arrow, *B*) and grossly invisible carcinoma in situ (large arrow, *C*).
(Case courtesy Dr. Rolf Schade, Birmingham, UK.)

Histology

In its classical form, flat carcinoma in situ is recognized histologically as an abnormality of the urothelium composed of **cancer cells throughout its thickness**. The **thickness** of the cancerous epithelium is **variable**: some carcinomas in situ are composed of **only three or four layers of cells**, whereas others may be composed of **15 or even more layers of cells**. The cancer cells may vary in **size from large to very small**, corresponding to cell sizes observed in various forms of invasive urothelial carcinoma and the size of the cancer cells in the urinary sediment (Fig. 23-11A; see also Figs. 23-9D and 23-10C). The epithelium may sometimes show **differentiation in the superficial layers and the presence of umbrella cells on the surface**. Such lesions were sometimes referred to as “dysplasia” but in our experience,

P.788

the diagnosis of carcinoma in situ can be established even **if the malignant cells are confined to three or four basal layers of the epithelium**. We also observed a case of carcinoma in situ of the bladder composed of large cancer cells with **eosinophilic cytoplasm**, resembling oncocytes. **Extension of carcinoma in situ into the nests of von Brunn should not be considered as evidence of invasion** (Fig. 23-11A).

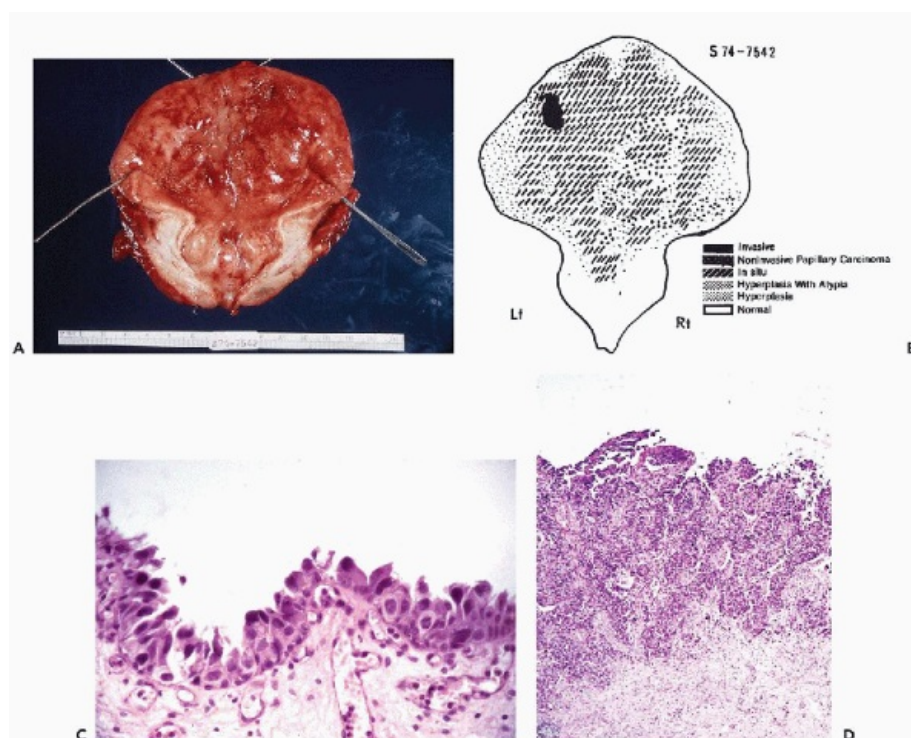

Figure 23-10 Bladder removed by radical cystectomy for extensive carcinoma in situ. *A.* The gross appearance of the bladder with markedly reddened epithelium. *B.* Mapping of the bladder showing one focus of occult invasive carcinoma. *C.* Histologic appearance of carcinoma in situ lining much of the bladder surface. *D.* The focus of unexpected superficial invasive carcinoma. The patient remained free of disease for 10

years after cystectomy.

Another form of **carcinoma in situ** may mimic **Paget's disease** (Fig. 23-11D) and is characterized by the presence of **large cancer cells with clear cytoplasm** within a relatively unremarkable epithelium (Koss, 1975; Yamada et al, 1984). It is of note that the **pattern of Paget's disease is repeated in the epithelia of the vulva, vagina, and penis in metastatic urothelial carcinoma** to these organs. Dr. Melamed observed a case of **carcinoma in situ of the bladder infiltrated by large macrophages**, mimicking Paget's disease.

Because the cancerous epithelium is fragile, sometimes only the **frayed remains of bottom layers may be observed in the biopsy** (Fig. 23-11C). The term "**denuding cystitis**" (Elliot et al, 1973) or, more recently, "**clinging variant of carcinoma in situ**" has been proposed to describe this phenomenon (Epstein et al, 1998). McKenney et al (2003) provided a comprehensive review of histologic patterns of urothelial carcinoma in situ.

Carcinoma in situ may be **multicentric** and involve several areas of the urothelium. As documented by biopsies of workers exposed to carcinogens, these lesions were **most often observed in the floor of the bladder** (the trigone area), including the periureteral areas, **followed by bladder neck**. The posterior and lateral walls of the

P.789

bladder were next in frequency of involvement. The anterior wall or the dome were rarely involved. Cheng et al (2000A) confirmed that the trigone of the bladder was most often affected.

Figure 23-11 Various forms of carcinoma in situ. *A.* Lesion composed of large cells extending to nests of Brunner. *B.* Lesion composed of medium-sized cells. *C.* Lesion showing residual small cancer cells attached to the surface of the bladder ("clinging type"). *D.* Pagetoid type of carcinoma in situ with numerous clear cells in the epithelium.

Carcinoma in situ may **extend to the distal ureters and the urethra in both female and male patients** (De Paepe et al, 1990; see Fig. 23-22). An **extension of carcinoma in situ of the bladder into the prostatic ducts is an important complication of this disease** (see Fig. 23-24). **This was observed in 9 of 20 cystectomy specimens with high-grade urothelial cancer** studied by complete mapping by Mahadevia et al (1986). **This observation**

has a major impact on treatment options because the tumor in the prostatic ducts is not accessible to and does not respond to immunotherapy with bacillus Calmette-Guérin (BCG).

Behavior

The most important property of flat carcinoma in situ is its **progression to invasive carcinoma**. The invasion into lamina propria usually occurs in the form of **broad bands, sharp tongues, or single cancer cells** (see Fig. 23-10). Because invasion occurs from the deeper portions of the cancerous epithelium, it may completely escape the attention of the urologist, even in patients under close surveillance. The **rate of progression of untreated carcinoma in situ to invasive cancer is about 60% in 5 years** (summary in Koss, 1975). Similar observations were reported by Utz et al (1970), Schade and Swinney (1973), and Farrow et al (1977). In a recent paper from the Mayo Clinic, **15-year survival** of 138 patients with this disease was reported to be **below 50%**, even though 41 patients received immediate and 34 delayed cystectomy (Cheng et al, 1999A). Most patients died of invasive and metastatic urothelial carcinoma.

Transit Time of Flat Carcinoma In Situ to Invasive Cancer

Follow-up data obtained on industrial workers and narrated below suggested that **progression of carcinoma in situ to invasive cancer can be rapid in some patients and occur within 2 years** after discovery. In other patients, however, the progression took up to 12 years (Table 23-3). These data were similar to those reported by Melamed et al (1964), which pertained to patients without carcinogen exposure seen at the Memorial and James Ewing Hospitals (Fig. 23-12). Additional data on several personally observed patients with sessile carcinoma in situ of the bladder, occurring ab initio, support the view that **from 2 to 7 years elapse from the time of initial cytologic observation until the development of invasive urothelial carcinoma**. Cheng et al (1999A) reported that the mean time interval for progression from carcinoma in situ to invasive cancer was 5 years. **These data confirm that urothelial carcinoma in situ of**

P.790

the bladder is a life-threatening disease capable of progression to invasive cancer within a relatively short period of time.

TABLE 23-3 DURATION OF SUSPICIOUS OR POSITIVE CYTOLOGY UNTIL HISTOLOGIC PROOF OF CARCINOMA - COMPARISON OF DATA FROM 1969 AND 1965				
Duration	1969		1965	
	Prior carcinoma	No prior carcinoma	Prior carcinoma	No prior carcinoma
<1 yr	1	6	0	0
12-20 mo	0	2	2*	1

21-32 mo	1	2	1	2
33-38 mo	1	1	2	1
50 mo	0	0	1	0
60 mo	0	1	0	0
77 mo	0	0	0	1
Total (26 patients)	3	12	6	5

(Koss LG, et al. Further cytologic and histologic studies of bladder lesions in workers exposed to para-aminodiphenyl: progress report. JNCI 43:233-243, 1969.)

* One patient with papilloma only.

Prout et al (1983, 1987) suggested that there were **differences in behavior of primary carcinoma in situ when compared with the secondary lesions of this type, preceded by or accompanying papillary tumors**. These authors claimed that the progression of the "secondary" carcinoma in situ to invasive cancer is less likely to occur. However, in our experience, the difference, if any, is not significant, as documented in Figure 23-12.

The principal features of carcinoma in situ of the urinary bladder are summarized in

Table 23-4. The therapy of these lesions is discussed in the closing pages of this chapter.

Urothelial Atypia or Atypical Urothelial Hyperplasia (UIN-I or Low-Grade IUN)

As shown in Figure 23-13A, the **nuclei of urothelial cells show moderate nuclear enlargement, but no significant hyperchromasia**. This epithelial abnormality is often associated with, and may be, a **precursor lesion of papillary**

P.791

tumors, but its exact prospective significance is not fully known. I have not seen an invasive cancer derived from this level of urothelial abnormality. **In cytologic samples, slight atypia of urothelial cells, rarely of diagnostic significance, may be observed in the presence of this lesion.**

TABLE 23-4 CHARACTERISTICS OF NONPAPILLARY CARCINOMA IN SITU OF THE BLADDER

- The lesion cannot be recognized cystoscopically as a tumor.
- Cystoscopic abnormalities may mimic inflammation; “velvety redness,” “cobblestone epithelium,” or “interstitial cystitis” were recorded. In other cases there are no cystoscopic abnormalities whatever.
- The lesion may extend into the ureters.
- In males, the lesion often extends into the prostatic ducts and the penile urethra.
- Because the lesion produces only nonspecific symptoms or may be asymptomatic, its diagnosis is based either on cytology of voided urine or on incidental biopsies of bladder epithelium.
- If untreated, carcinoma in situ will progress to invasive carcinoma in at least 60% of all patients within 5 years.

Markedly Atypical Urothelial Hyperplasia (Dysplasia, IUN-II, High-Grade IUN)

As shown in Figure 23-13B, the urothelium shows **markedly abnormal, enlarged and hyperchromatic nuclei**. Although **the degree of abnormality is perhaps somewhat less than in classic carcinoma in situ** (see Fig. 23-11), **the morphologic separation of the two lesions is highly subjective**. This type of lesion has been designated as “**dysplasia**” (Murphy and Soloway, 1982) or “**carcinoma in situ, grade II**” (Mostofi, 1979). The lesion was recently shown to have similar proliferative index and expression of p53 gene as classical carcinoma in situ (Cina et al, 2001).

In my experience, **this lesion is equivalent in its biologic behavior to carcinoma in situ** (Fig. 23-13C,D) in that it has a high potential for progression to invasive cancer, an observation confirmed by others (Wolf and Hjogaard, 1983; Harving et al, 1988; Rosenkiede et al, 1988). In a more recent study, the **progression of primary dysplasia, either to classical carcinoma in situ or to invasive cancer**, occurred in 7 of 36 patients (Cheng et al, 1999B). **These lesions cannot be differentiated cytologically from carcinoma in situ.**

Clinical Significance of Intraurothelial Neoplasia

In 1960, Eisenberg et al noted that the **prognosis of papillary tumors of the bladder was**

related to abnormalities in peripheral urothelium adjacent to tumors. In patients with atypical peripheral epithelium, the probability of recurrent tumor or invasive cancer was significantly greater than in patients with normal urothelium. This casual observation was repeatedly confirmed in retrospective studies of bladder tumors by mapping (Koss et al, 1974, 1977; Koss, 1979) and in a prospective study by Althausen et al (1976), shown in Table 23-5. It may be noted that **the probability of occurrence of invasive cancer in patients with urothelial abnormalities increases with the level of atypia** and is very high for patients with peripheral carcinoma in situ.

CYTOLOGY OF TUMORS OF THE BLADDER

Lessons From Long-Term Follow-Up Study of Industrial Workers Exposed to Carcinogens

The **value and the efficacy of urinary tract cytology** could be documented during a 12-year follow-up of a group of about 500 workers exposed to a **potent bladder carcinogen, *p*-aminodiphenyl**. Following the example of Crabbe, who initiated cytologic screening of high-risk industrial workers in the United Kingdom (summary in Crabbe, 1961), the study was based on analysis of **cytologic findings in the sediment of voided urine and biopsy documentation of urothelial tumors** (Melamed et al, 1960; Koss et al, 1965, 1969). In this cohort, invasive carcinoma of the bladder developed in about 10% of the workers during the follow-up period.

p-aminodiphenyl is inhaled and the products of its metabolism are excreted in the urine within 48 to 72 hours after exposure. The initial exposure is usually accompanied by an episode of transient hematuria, with a prompt return to normalcy. There is no evidence that either *p*-aminodiphenyl or its metabolites are stored in the body. Hence, it has to be assumed that the genetic damage to the cells of the bladder epithelium, of as yet unknown nature, occurs during the few hours following exposure, even though it may not manifest itself clinically for many years. There appears to be **no direct correlation between the amount and length of exposure to carcinogens and the development of cancer of the bladder** (Koss et al, 1965). Persons with a casual contact with the carcinogen may develop carcinoma of the bladder, whereas numerous others with prolonged contact may remain free of disease for many years. Thus, a process of natural selection of an unknown nature protects some people from cancer of the bladder, even under most unfavorable conditions.

Following the initial effects of exposure to carcinogens, there was a period of clinical normalcy of unpredictable duration, often lasting as long as 10 to 15 years or more. During this period, the **cytologic findings** in the urinary sediment were normal. **Low-grade papillary tumors that occurred in some workers as the initial lesion could not be identified in the urinary sediment.**

Subsequently, in some of the exposed workers, slight and poorly defined cytologic abnormalities were observed in the

P.792

urinary sediment. The most conspicuous change, **limited to a very few cells**, was a **slight enlargement of the nuclei** of the urothelial cells, which in an occasional patient was **associated with slight hyperchromasia**, somewhat comparable to the "dyskaryosis" (or dysplasia) of squamous cells, observed during the formative stages of cervix cancer (see Chap. 11). The "dyskaryotic" cells, diagnosed as "atypia," appeared in the urine intermittently,

sometimes over a period of several years. The cystoscopic findings in patients during this stage of the disease were essentially negative although, occasionally, an area of redness or “cystitis” was observed, which on biopsy, disclosed urothelial hyperplasia with slight nuclear abnormalities (see Fig. 23-17). In general, the cytologic findings during this period were not predictive of subsequent malignant events.

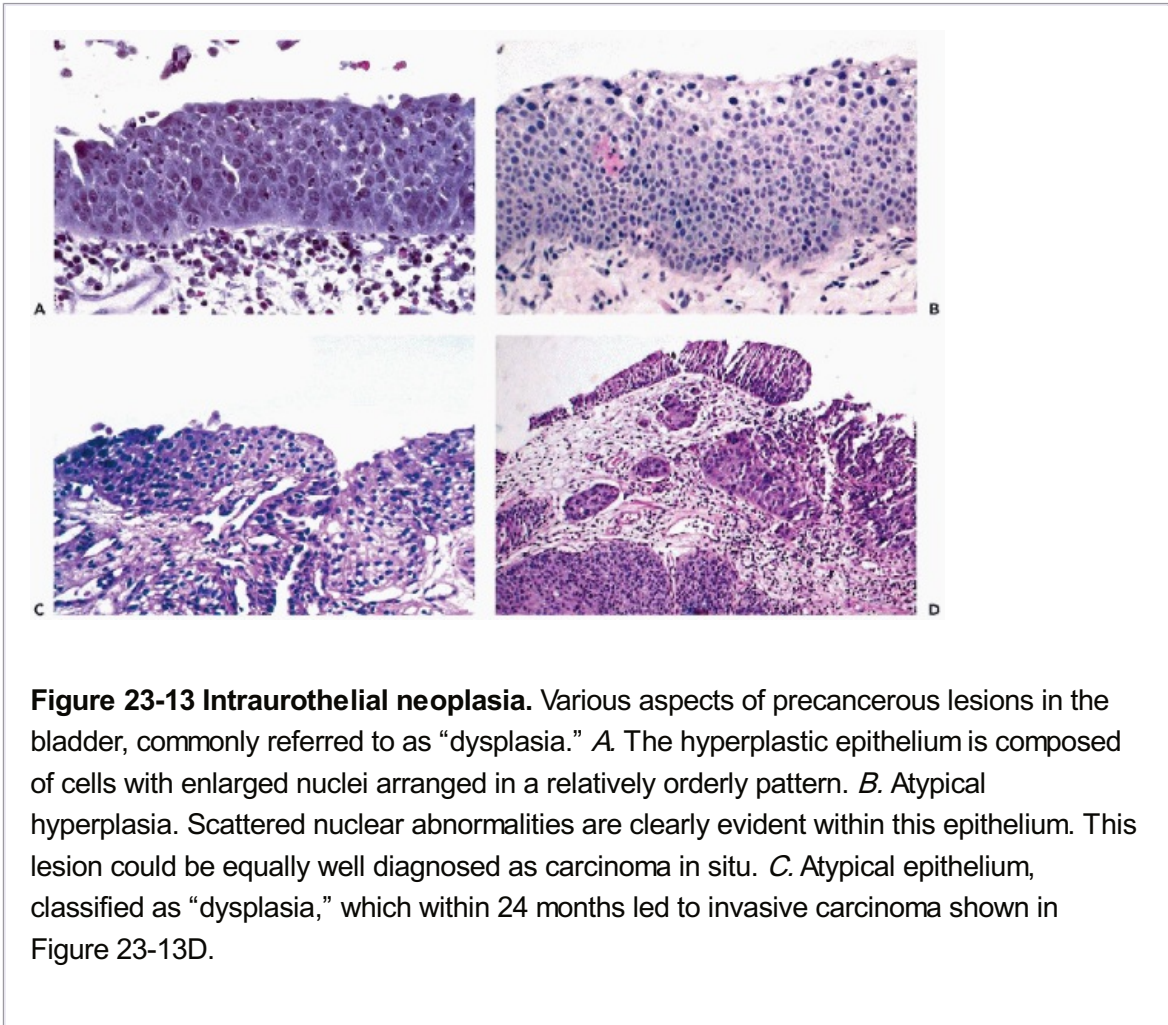

TABLE 23-5 DEVELOPMENT OF INVASIVE BLADDER CANCER IN PATIENTS WITH GRADE I OR II PAPILLARY TUMORS WITHIN 5 YEARS, ACCORDING TO STATUS OF PERIPHERAL EPITHELIUM

Status of Peripheral Epithelium	No. Patients	Development of Invasive Cancer No. Patients (%)	
Normal	41	3	7
Atypia	25	9	36
Carcinoma in situ	12	10	83
TOTAL	78	22	

(Althausen AF, et al. Non-invasive papillary carcinoma of the bladder associated with carcinoma in situ. J Urol 116:575-580, 1976, with permission.)

The Stage of Positive Cytology

After an unpredictably long period of either negative cytologic findings or slight cytologic abnormalities, there followed a period of clearly **positive cytologic findings**, associated with **papillary or nonpapillary high-grade bladder cancer or with flat carcinoma in situ**. In most patients, the **appearance of the cancer cells was sudden**, suggesting that the **development of high-grade malignant lesions in**

P.793

the bladder is not necessarily preceded by diagnosable precursor stages. During this study, which was conducted many years ago with a group of general urologists, it proved difficult to obtain the biopsy confirmation of carcinoma in situ, particularly because many patients harboring this deadly disease were asymptomatic and their bladders showed no evidence of tumor on cystoscopy. Still, in many patients, biopsies were obtained and confirmed the presence of carcinoma in situ. This study documented that **cytology of voided urine is most useful in the discovery of high-grade urothelial tumors and notably flat carcinoma in situ of the bladder** (Melamed et al, 1960). Schulte et al (1986) and Crosby et al (1991) made fundamentally similar observations on a cohort of workers exposed to **β -naphthylamine and benzidine**.

Progression to Invasive Carcinoma

The follow-up studies on workers exposed to *p*-aminodiphenyl permitted the accumulation of data pertaining to the **duration of the stage of carcinoma in situ, as diagnosed cytologically**. In this group of patients, treatment was usually not instituted before the appearance of a clinically identifiable tumor. This experience is summarized in Table 23-3. At the conclusion of this study in 1970, there were 13 histologically documented instances of primary nonpapillary carcinoma in situ. In 7 of these patients, **invasive carcinoma developed within 1 or 2 years** after the initial cytologic diagnosis. The longest time interval observed was 12 years (Koss et al, 1969). **These data confirmed that urinary cytology is most useful in the discovery of precursor lesions of invasive cancer, notably flat carcinoma in situ, but has limited value in the diagnosis of urothelial abnormalities preceding this lesion**.

Comparison of Precancerous Events in the Bladder with the Uterine Cervix

The genesis of human bladder cancer may be compared with the processes within the human cervix, the only organ that has had the benefit of similar sustained investigative attention. In the cervix, there is usually clear cut-evidence of cytologic abnormalities prior to the development of high-grade lesions (see Chap. 11). In the urinary bladder, cytologic abnormalities preceding carcinoma in situ were either absent, or at best, not well defined and intermittent. Thus, **the option of early cancer prevention, which is paramount in cytologic screening for cancer of the uterine cervix is, at best, slight for the urinary bladder and limited to the discovery of carcinoma in situ and related lesions that are dangerous to the patient**. Although progression or regressions of high-grade cervical lesions may occur, the regression of untreated carcinoma in situ of the bladder appears to be extremely rare. Another **major difference between the cervix and the bladder is the time lapse between the**

occurrence of carcinoma in situ and its progression to invasive carcinoma: this appears to be considerably shorter for the urinary bladder.

Urothelial Tumors

Targets of Cytologic Investigation

The success or failure of cytologic investigations of the urothelial tumors of the bladder, ureters, or the renal pelvis depends on morphology of the lesion. Thus, simple hyperplasias and low-grade papillary urothelial tumors that are characterized by either normal urothelium or by a urothelium with only slight and focal nuclear abnormalities, cannot be identified in cytologic material with any degree of certainty unless one is willing to assume responsibility for a large number of false-positive alarms. Cytology of the urinary tract is useful only in the identification of tumors or conditions that are associated with perceptible morphologic abnormalities of cells, hence, tumors of high-grade, with emphasis on flat carcinoma in situ and related lesions.

Thus, the primary areas of application of cytologic techniques to the urinary tract are:

- **Detection and diagnosis of high-grade urothelial tumors**
- **Monitoring of patients after treatment for neoplastic lesions of the lower urinary tract, regardless of type or grade, because of risk for development of new high-grade lesions**
- **Under special circumstances, monitoring of high-risk, asymptomatic industrial workers exposed to known carcinogens. The benefits of this approach are discussed further in this chapter.**

Some caveats.

The cytologic diagnosis of neoplastic urothelial lesions is difficult. Some of the reasons for the diagnostic problems, already discussed in Chapter 22, are repeated here:

- **The recognition of limitations of cytology of the urinary tract in the diagnosis of low-grade papillary tumors, by avoiding mistakes in the interpretation of benign cell changes, particularly those induced by inflammation, instrumentation, or lithiasis (stones)**
- **Mistakes in the interpretation of polyomavirus-infected cells for cancer cells**
- **Mistakes in the interpretation of cell abnormalities induced by or associated with therapy**

Because the accuracy of the diagnosis relies often on subtle cytologic abnormalities, **impeccable technical processing of samples** is essential, as discussed in Chapters 22 and 44.

Urothelial Cancer Cells

The appearance of urothelial cancer cells **differs somewhat according to the medium of diagnosis, voided urine or bladder barbotage.**

Voided Urine

Depending on tumor type and grade, the **urothelial cancer cells vary in size** and may be equal to, **smaller, or larger than normal urothelial cells.** In voided urine, the cancer cells occur **singly** or in **small, loosely structured clusters.** Large

aggregates of cancer cells are very uncommon, although they occur in specimens processed by the ThinPrep method.

The **configuration of cancer cells is variable**. Most of them are **approximately spherical or oval** with an irregular outline, but elongated or bizarre cell shapes have been observed, particularly in high-grade tumors. **Columnar cancer cells** and **large multinucleated cells mimicking umbrella cells** may be observed. The **cytoplasm is usually basophilic** and in well-preserved cells, **has sharp borders**; however, cells in voided urine are often **poorly preserved and the cytoplasm is frayed**. Cells with **eosinophilic cytoplasm** may occur, particularly if there is a **squamous component to the tumor**. **Cytoplasmic vacuoles** and nonspecific red inclusions are sometimes observed (Fig. 23-14).

The **nuclei of cancer cells are, as a rule, large for cell size and therefore there is a conspicuous change in the nucleocytoplasmic ratio in favor of the nuclei**. The nuclei are typically of **irregular, abnormal shape**, although some are approximately spherical or oval, sometimes showing small peripheral protrusions on close inspection. The most **important nuclear abnormality in urothelial cancer is hyperchromasia caused by abnormal nuclear texture**: the chromatin is arranged in large, coarse, tightly packed or superimposed granules, rendering the nucleus dark and nontransparent (Fig. 23-15). This is in marked **contrast with benign cells**, which have a **finely textured “salt-and-pepper” appearance** due to small chromatin granules, separated from each other by areas of translucent nucleoplasm (Fig. 23-15A-G). Practically speaking, one can “see through” a normal nucleus but not through the nucleus of a cancer cell. In **high-grade tumors, abnormal mitotic figures are fairly common in the sediment** (Fig. 23-15H). **Multiple and large nucleoli may occasionally be present, particularly in flat carcinoma in situ and in invasive cancer, but they are much more difficult to see in voided urine** than in barbotage specimens, because of the marked nuclear hyperchromasia (Fig. 23-15G).

Figure 23-14 Cancer cells in urinary sediment. A. Several large cancer cells with very large, coarsely granulated, irregularly shaped nuclei. B. Cancer cells, appearing singly and in clusters, in voided urine sediment (ThinPrep). C. Invasive carcinoma corresponding to

the smear shown in *B. D.* Small cell urothelial carcinoma in urinary sediment. (*A*: oil immersion.)

Except for the cells mimicking umbrella cells, we have not observed any cancer cell types that could be considered typical or unique of urothelial carcinoma. Although bizarre cell forms may occur in high-grade tumors, we have not observed **in voided urine, the elongated cells with long cytoplasmic processes with either bulbous or flattened ends (“fish tail” or “cercariform cells”)** that were described as characteristic of metastatic urothelial cancer in aspirated samples (Johnson and Kini, 1993; Powers and Elbadawi, 1995; Renshaw and Madge, 1997; Hida and Gupta, 1999). It is possible that these authors classified the common columnar-shaped cancer cells, such as shown in Figure 23-15D, as “cercariform cells.”

P.795

Figure 23-15 Oil immersion photographs comparing benign urothelial cell shown in *A*, with cancer cells shown in *B-H*. The differences in the nuclear structure are evident: the nuclei of cancer cells are significantly larger, coarsely granular, and show slight

irregularities of contour. The cell in *D* has a columnar configuration. This is a common finding in bladder cancer. *E*. Shows a binucleated cancer cell. *F*. Shows a cancer cell with eosinophilic cytoplasmic inclusions. *G*. Cancer cell with prominent nucleoli. *H*. An abnormal mitotic figure.

P.796

Differential Diagnosis

Perhaps the most important points of **differential diagnosis** of urothelial cancer are urothelial cells infected with **polyomaviruses that show large, homogeneous, basophilic nuclear inclusions**. As discussed at length in Chapter 22, such cells are readily confused with cancer cells. We observed that in some specimens **processed by reverse filtration (ThinPrep)**, the inclusions can be fractured. Other potential sources of error include the uncommon **pyknosis of normal nuclei, nuclear changes in lithiasis**, and in nuclear abnormalities **induced by treatment**, all discussed in Chapter 22. Errors can be avoided if the **high nucleocytoplasmic ratio** and the **granularity of the hyperchromatic nuclei**, such as shown in Figure 23-15, are considered essential criteria of diagnosis of urothelial cancer in well-preserved **single cells**.

Based on the degree of cell abnormalities and cell size in voided urine sediment, Bergkvist et al (1965) performed **grading of urothelial bladder tumors** and claimed high level of prognostic accuracy. Tumors with smaller cancer cells were considered to be of a higher grade than tumors with larger cells. This concept has received support from Esposti and Zajicek (1972) and Suprun and Bitterman (1975) but was not universally accepted and was replaced by image analysis and flow cytometry (see below).

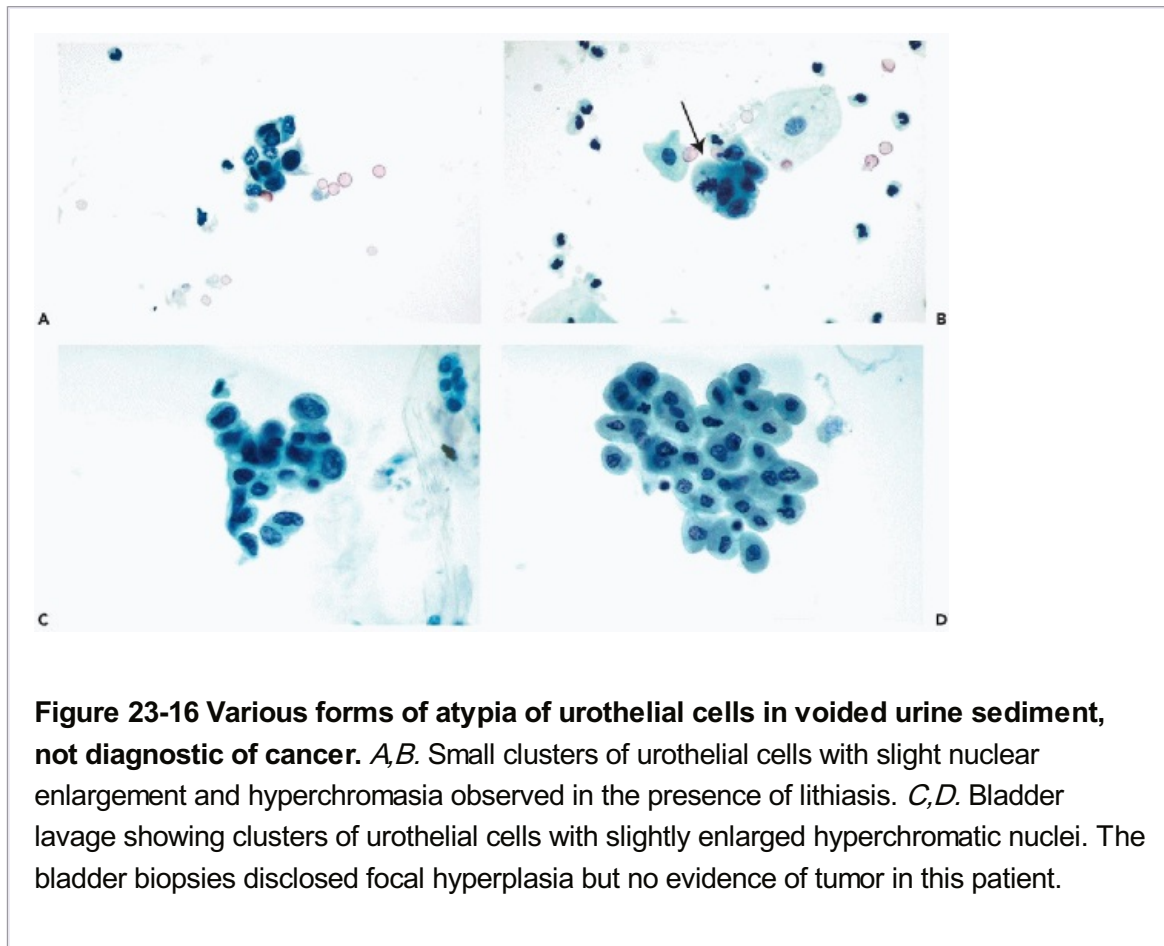

Figure 23-16 Various forms of atypia of urothelial cells in voided urine sediment, not diagnostic of cancer. A,B. Small clusters of urothelial cells with slight nuclear enlargement and hyperchromasia observed in the presence of lithiasis. **C,D.** Bladder lavage showing clusters of urothelial cells with slightly enlarged hyperchromatic nuclei. The bladder biopsies disclosed focal hyperplasia but no evidence of tumor in this patient.

Bladder Barbotage (Washings)

For description of technique of bladder barbotage, see Chapter 22. In this type of material, all cells, including cancer cells, are usually better preserved than in voided urine and their cytoplasm is more likely to be intact. The general features of cancer cells described above, that is, **variability in size and configuration and altered nucleocytoplasmic ratio, are evident**. The **nuclear texture** is also altered but the **degree of nuclear hyperchromasia is usually less** than in voided urine and the **nuclei are more transparent**. **Conspicuous, large, irregular, and sometimes multiple nucleoli** are much more common in cancer cells in bladder barbotage than in voided urine (Fig. 23-15G). A **word of caution** is necessary: in specimens processed by a proprietary procedure known as **ThinPrep, the chromocenters in normal urothelial cells, particularly the umbrella cells, may stain pink and may mimic nucleoli**. Experience with this technique is necessary to avoid errors of interpretation.

Scanning Electron Microscopy of Urothelial Cancer Cells

Jacobs et al reported in 1976, the results of scanning electron microscopy of cell surfaces in experimental bladder cancer. The presence of **irregular surface microvilli** may be observed

P.797

during the early stages of carcinogenesis. The applicability of this method to the human urinary sediment was tested in our laboratories (Domagala et al, 1979). The studies disclosed poor preservation of many urothelial cancer cells with loss of surface structure. Some, but not all, of the **better-preserved cancer cells had numerous surface microvilli of uneven length and configuration**, similar to those observed in cancer cells in effusion (see Chap. 26). By contrast, the surfaces of benign urothelial and some squamous cells showed only sparse microvilli of fairly regular configuration. This method is theoretically of diagnostic value but it is too costly and time consuming to be applicable to the practice of cytopathology.

Atypical Urothelial Cells

Atypical urothelial cells are a **common finding, particularly in voided urine and bladder barbotage, in inflammatory conditions, lithiasis, systemic therapy with alkylating drugs, or intravesical therapy**, and may also occur in **urothelial tumors of all grades**. The atypical cells are usually small, show **nuclear enlargement with a slight change in the nucleocytoplasmic ratio and a slight to moderate increase in nuclear hyperchromasia**, usually below the level of hyperchromasia and granularity of chromatin associated with obvious cancer (Fig. 23-16). Mitotic figures may be present (Fig. 23-16B, arrow). The term “**dysplastic cells**,” proposed by Murphy (2000) in reference to small urothelial cells with enlarged nuclei, is **not justified**, as it implies a neoplastic event, whereas such cells may occur in a variety of benign situations and their origin in a specific epithelial abnormality is impossible to prove, even in the presence of a tumor.

Figure 23-17 Oil immersion images of cells classified as markedly atypical or suspicious. The cells show no significant change in the nucleocytoplasmic ratio. The nuclei are generally spherical, although somewhat hyperchromatic and granular. In the presence of such cells, a search for a bladder tumor is mandatory.

The “atypical” urothelial cells may also occur in low-grade tumors, discussed below. In some cases, **the separation of “atypical” from “suspicious” or outright malignant cells** may become a matter for a debate that is not easily settled (Fig. 23-17). In such cases, it is important to secure a patient's history and cystoscopic findings before formulating a clinical recommendation. Usually, the significance of the “atypical” cells will be fairly easily determined. Still, in some cases, long-term follow-up and multiple bladder biopsies may be required to rule out a neoplastic process.

In a **computerized image analysis study** of atypical cells, an attempt was made to determine whether the atypical cells originating in benign conditions could be separated from those associated with urothelial tumors. Statistical analysis of several computer-generated features suggested that the atypical urothelial cells could be divided into two groups, one sharing cell features with benign cells and the other with malignant cells (Koss et al, 1977). On subsequent microscopic review, the urothelial cells with nuclei of round or oval configuration and only slight to moderate increase

P.798

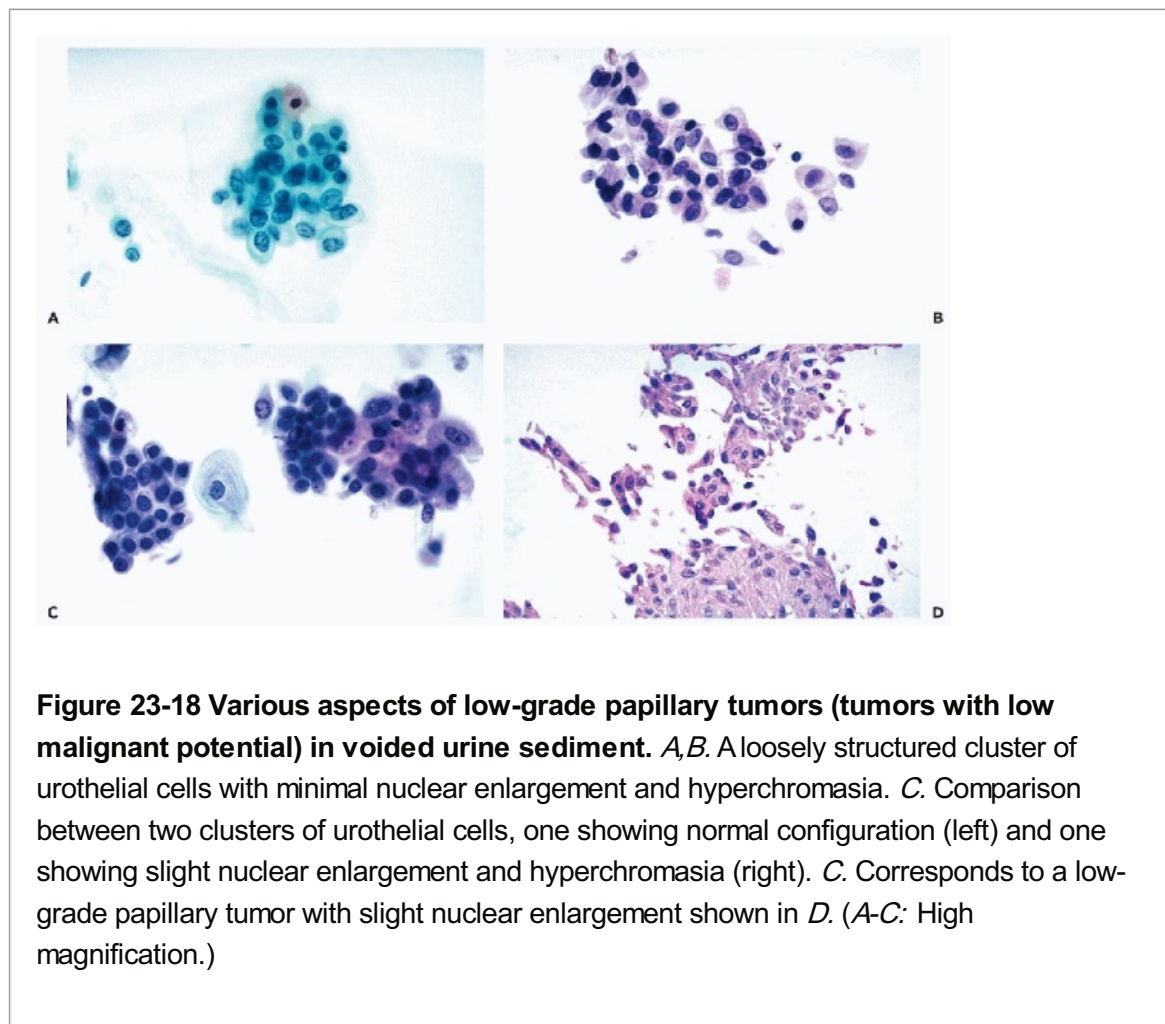

in hyperchromasia belonged to the first group (ATY-I) whereas cells with irregular configuration of cytoplasm and nuclei and greater nuclear hyperchromasia, classed as atypical II (ATY-II) (Fig. 23-17), were commonly associated with bladder cancer (Koss et al, 1978). Unfortunately, the data obtained by a complex computer analysis of cell features were of little value in routine microscopic studies of the urinary sediment.

There is good evidence that the **DNA of nuclei of urothelial cells goes hand-in-hand with the level of cytologic abnormalities** (Koss et al, 1985). Thus, **atypical cells with abnormal (aneuploid) DNA content may belong to the “possibly malignant” group.** The **application of DNA measurements and other ancillary procedures to the analysis of atypical cells is discussed below, but in our view, does not replace morphologic**

Recognition of Specific Types of Urothelial Tumors in Urinary Sediment

Papillary Tumors of Low Grade (Papillomas and Grade I Papillary Tumors of Low Malignant Potential)

In the presence of these tumors, the **background of the cytologic preparations is usually clean** and there is rarely any evidence of inflammation or necrosis. Erythrocytes in varying numbers are usually present. By definition, these tumors are **lined by normal or only slightly abnormal, though sometimes thickened, urothelium** (see above). Hence, **cells derived therefrom cannot be identified as malignant**. The changes in **individual urothelial cells are nonspecific** and the feature of **slight nuclear enlargement**, proposed by Murphy (2000) as a characteristic of these tumors, **is not reliable because such changes may occur under a variety of benign circumstances**. Further, such atypical cells are more likely to occur in papillary carcinomas of low grade (see below).

It has been suggested that there are some **differences in the configuration of cell clusters** between low-grade papillary tumors and normal urothelium (Kannan and Bose, 1993). It is true that the surface of the clusters of normal urothelium is often composed of semilunar umbrella cells with smooth surface, as discussed in Chapter 22 and shown in Figure 22-10. However, clusters with “ragged borders” may also occur in a variety of benign conditions, such as instrumentation, inflammation, or stones (lithiasis) (Fig. 23-18A,B). The latter condition, named “**calculus artifact**,” was discussed at length in a study by Kannan and Gupta (1999), who

documented the presence of cell clusters

P.799

with irregular borders and slight level of nuclear atypia in 46 of 65 patients with lithiasis (also see discussion of lithiasis in Chap. 22).

Nasuti et al (2001) studied the frequency of **tissue fragments** captured on the surfaces of **filters** in 2,553 voided urine sediments. There were 174 patients with bladder biopsies. These authors concluded that **tissue fragments, particularly of tri-dimensional configuration, were more common in patients with urothelial tumors of various grades than in negative controls**. This has not been our experience. In a similar study of 5,001 urine specimens processed by **cytocentrifugation**, Goldstein et al (1998) failed to observe this relationship. Neither paper addressed the issue of instrumentation, such as cystoscopy, that may have been the cause of the tissue fragments, particularly in patients suspect of harboring a bladder tumor.

Wolinska et al (1985) systematically compared the findings in **voided urine sediment** from 51 patients known to have low-grade papillary tumors and 30 controls. The material was obtained from patients without prior cystoscopy. Except for somewhat increased cellularity and occasional presence of atypical cell shapes, such as elongated cells, there were no diagnostic findings of note, **confirming that the cytologic diagnosis of low-grade papillary tumors cannot be reliably established**. Similar conclusions have been reached by the Swedish investigators, Esposti and Zajicek (1972). Kern (1975), using planimetric studies, confirmed the essentially normal configuration of cells derived from such tumors. These observations, and our experience, strongly contradict Murphy et al (1984), who claimed that low-grade papillary tumors could be identified in 62% of patients, a view that was moderated in Murphy's subsequent publication (2000).

Direct washings or brushings of the urinary bladder contribute little to the diagnosis of low-grade papillary tumors. Harris et al (1971) were able to **diagnose such lesions only in cell blocks of the urinary sediment, wherein biopsy-sized fragments of such tumors were observed**. However, fragments of urothelium **may also occur in spontaneously voided urine in the absence of a tumor**, particularly after instrumentation (see Fig. 22-10). Within recent years, several attempts have been made to revive the matter of cytologic diagnosis of low-grade papillary tumors, predictably with conflicting results. Thus, Raab et al (1994), using logistic regression analysis of numerous parameters, suggested that **irregular nuclear borders, increased nucleocytoplasmic ratio, and cytoplasmic homogeneity** of urothelial cells in bladder washings were highly specific for low-grade tumors. The same group of investigators confirmed that the three criteria are valid in ThinPrep preparations with a sensitivity of 59% and specificity of 100% (Xin et al, 2003). Although the first two criteria may have some value, the "cytoplasmic homogeneity" is puzzling as it is clearly not related to the nature of these tumors. Renshaw et al (1996) failed to confirm these observations. Bastacky et al (1999) also were unable to recognize cell features characteristic of low-grade lesions. Sack et al (1995), in a cohort of 208 patients, recognized low-grade papillary tumors in 11 of 33 such patients but also committed an equal number of false-positive errors. **Thus, cytology of the urinary sediment does not lend itself to the diagnosis of papillary tumors of low grade.**

There are **rare exceptions to this rule**: the finding of a **papillary cluster of urothelial cells with a central capillary** strongly suggests that the **cell cluster represents a broken fragment of a papillary tumor** (Fig. 23-19A). Also, **in the rare papillary tumors with a dominant squamous component, the cytologic findings can be suggestive of this**

diagnosis (Fig. 23-19B,C).

On the other hand, if the urinary sediment shows obvious cancer cells and the biopsy discloses only a low-grade papillary lesion, the cytologic finding is of great clinical importance: it strongly suggests that a high-grade malignant lesion is present in the urinary tract. This may be another papillary lesion of high grade or, more often, nonpapillary carcinoma, in situ or invasive, located in the bladder, ureters, renal pelvis, or even within the prostatic ducts and the urethra. **Every effort must be made to localize and evaluate this lesion or lesions, because of their ominous prognosis.**

Papillary Tumors of High Grade (Papillary Carcinomas, Grades II and III)

In the urinary sediment, most of these lesions are characterized by the presence of **markedly atypical urothelial cells and recognizable cancer cells, occurring singly or in loosely structured clusters**. The number of single cancer cells increases with tumor grade. There are some important differences between the cytologic presentation of papillary tumors grade II and tumors grade III.

Papillary Tumors Grade II (Papillary Carcinomas, Low Grade)

Not all grade II tumors can be recognized cytologically. In 20 of 68 such tumors studied by Koss et al (1985), **only benign or somewhat atypical urothelial cells were observed, and the diagnosis could not be established** (Fig. 23-20). These were most likely grade II tumors with a DNA content in the diploid range. In aneuploid papillary tumors, grade II, **markedly atypical or frankly malignant cells can be recognized, either singly or in small clusters**. The cancer cells are **usually of medium size and rarely show marked abnormalities of configuration**, as in tumors of higher grade. The performance of cytology in debatable cases with "atypical," but not definitely malignant, cells can be improved by **analysis of DNA pattern**. Abnormal (aneuploid) DNA values are strongly suggestive of a neoplastic event. A number of new technological developments are also designed to recognize papillary tumors with negative or questionable cytologic presentation, with **fluorescent in situ hybridization (FISH)** being the most secure. These diagnostic options are discussed further on in this chapter.

Papillary Tumors Grade III (Papillary Carcinomas, High Grade)

All or nearly all papillary tumors grade III can be identified by cytology. These tumors shed **cancer cells that are of variable size and configuration** (Fig. 23-21). The papillary tumors, even highly anaplastic, may shed **cancer cells in**

P.800

large clusters, sometimes reminiscent of papillary arrangement of cells. However, **single cancer cells are always present and are usually numerous**. The **background** of smears often, but not always, shows evidence of **inflammation and necrosis**. Under these circumstances, it is impossible to determine whether or not a tumor is invasive and the variability in size and configuration of cancer cells is not helpful. It must be stressed that **in the presence of papillary tumors, particularly of high grades, the adjacent or remote peripheral urothelium of the bladder may show intraurothelial neoplasia of high grade (IUN III, equivalent of atypical hyperplasia or nonpapillary carcinoma in situ) whence occult invasion may take place** (see Fig. 23-4B).

Figure 23-19 Papillary tumor. *A* A remarkable example of fragments of papillary tumor with a capillary vessel in voided urine sediment. This appearance is diagnostic of a papillary tumor. *B, C* Histologic and cytologic aspects of a low-grade papillary tumor of the bladder with formation of squamous pearls, which were seen in the urinary sediment, shown in *C*. (*A-C*: High magnification; *A*: courtesy of Dr. June Koizumi, New York Hospital, NY.)

Work-Up of Patients with Papillary Tumors

Because patients with papillary tumors may also harbor flat neoplastic lesions, which are more likely to progress to invasion than papillary lesions, a complete evaluation of patients with papillary bladder tumors requires **not only a biopsy of the visible lesion, but also an evaluation of the remaining urothelium by cytologic examination of voided urine sediment and by multiple superficial biopsies of the bladder to rule out the presence of a nonpapillary lesion. This recommendation is particularly important if the urinary sediment remains positive after resection of visible papillary lesion(s).** The recommended minimum work-up of such patients calls for cytologic analysis of **three voided urine samples on three consecutive days for optimization of results.** The optimal approach to bladder biopsies is described below in reference to flat carcinoma in situ.

Nonpapillary Urothelial Carcinoma

Virtually all nonpapillary urothelial cancers, whether invasive or in situ, are made up of clearly identifiable cancer cells that can be readily recognized in the urinary sediment. **These lesions, particularly the nonpapillary carcinoma in situ and related lesions (IUN of high grade), are the principal target of cytologic studies of the urinary tract.**

Nonpapillary (Flat) Carcinoma In Situ

Voided urine sediment is the ideal diagnostic medium for the primary diagnosis of nonpapillary carcinoma in situ, whether located in the bladder, the renal pelvis, the ureters, or the urethra. Regardless of the method of preparation, the urinary sediment usually yields **persuasive evidence of cancer, reflecting the poor adhesiveness of cancer cells**

in the epithelial lesion (Figs. 23-22, 23-23, 23-24 and 23-25). Because the shedding of cancer cells is sometimes intermittent, **three specimens of voided urine obtained on consecutive days are a secure means of diagnosis** (Koss et al, 1985, 1995).

The most common cytologic presentation of flat carcinomas

P.801

in situ is a fairly **monotonous population of medium-sized or small urothelial cancer cells, comparable in size to benign urothelial cells from deeper layers of the urothelium**. The **cancer cells** usually appear **singly**, but occasionally form **small clusters**. **Occasionally, a few larger or bizarre cells may occur. Regardless of size, the cells have an irregular configuration and relatively scanty, usually basophilic cytoplasm, although cells with eosinophilic cytoplasm may occur.** The **nuclei** are relatively **large, hyperchromatic**, have an **irregular contour and show an abnormal chromatin texture**. A **coarse, filamentous arrangement of the chromatin is especially frequent**. **Enlarged nucleoli** are infrequent but may occasionally be noted. Condensation of nuclear chromatin or **pyknosis** is fairly common and, in such nuclei, the arrangement of chromatin cannot be studied.

Figure 23-20 Various aspects of cytologic presentation of a low-grade papillary tumor. A. Brush specimen showing a cluster of urothelial cells with somewhat enlarged and hyperchromatic nuclei that appear to center around a core, possibly muscularis mucosae. B,C. Voided urine. The cells show slight enlargement of the nuclei but no significant hyperchromasia or change in the nucleocytoplasmic ratio. The papillary tumor corresponding to B and C is shown in D. The cytologic diagnosis of tumor in such cases is extremely difficult and unreliable.

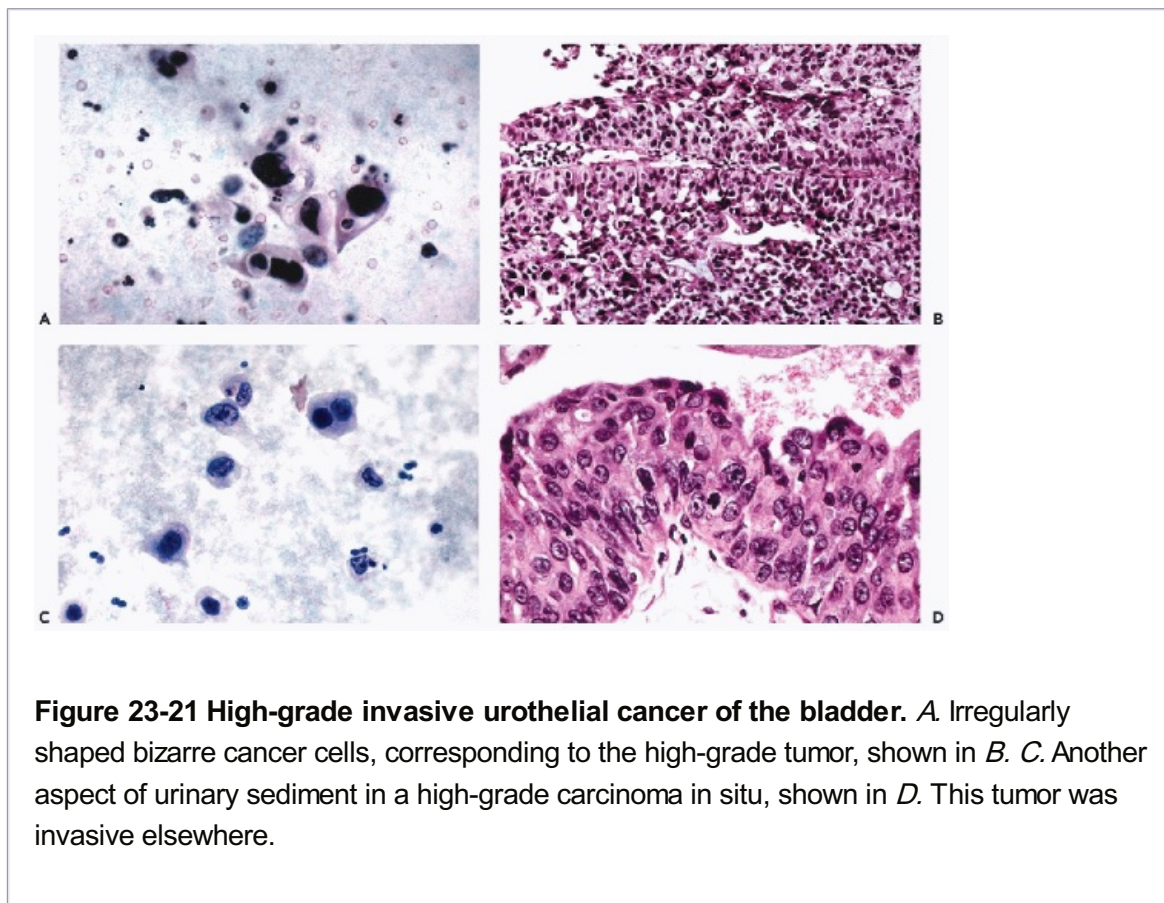

In the sediment of about one-third of the patients with flat carcinoma in situ, the population of cancer cells is pleomorphic (see Fig. 23-21C,D). **The cancer cells vary in size and configuration although their nuclear characteristics are the same. Such smear patterns can be separated from patterns of invasive carcinoma only by smear background.** In the presence of carcinoma in situ, the urine rarely contains more than a **few**

inflammatory cells or erythrocytes, and there is usually **little evidence of necrosis**, **whereas marked inflammation and necrosis are commonly observed in invasive cancer**. Rarely, the cellular aberrations in carcinoma in situ may be so inconspicuous that they are interpreted as inflammatory changes, a verdict that is usually contradicted by nuclear abnormalities. However, in most patients the diagnosis is obvious, provided that the sources of error in the recognition of cancer cells, discussed above, are eliminated. Extension of carcinoma in situ to the ureters (Fig. 23-22) or prostatic ducts (Fig. 23-24) does not change the smear pattern.

From our laboratory, Voutsas and Melamed (1963) reported a systematic cytologic study of 20 patients with urothelial carcinoma in situ of the bladder. This study generally confirmed the observations reported above. **The cell pattern did not differ whether the lesion was primary or secondary to a previously treated tumor of the bladder**. These authors pointed out that **following a biopsy or fulguration, there may be a marked alteration of the smear pattern**, usually appearing within 24 hours after the procedure and lasting up to 4 weeks. A general **increase in the**

P.802

number of both benign and malignant cells, and occasionally **bizarre cell changes mimicking radiation changes**, were observed following such procedures.

Boon et al (1986), who studied 13 patients with primary carcinoma in situ and 10 patients with secondary carcinoma in situ of the bladder, did not fully agree with the observations recorded above. She found preponderantly pleomorphic cancer cells in 21 patients and clusters of cancer cells in 19 of the 23 patients. The observed differences may be caused by a different patient population and a different technical approach to the study of the urinary sediment.

Clinical Handling and Confirmatory Biopsy of Carcinoma In Situ

An **unequivocal cytologic diagnosis of urothelial carcinoma in the absence of cystoscopic evidence of a bladder tumor is usually diagnostic of a flat carcinoma in situ**. This diagnosis is often perplexing to the unsuspecting urologist who must be persuaded to obtain **biopsies** of the bladder, even in the total absence of cystoscopic abnormalities.

Although on rare occasions the **cancer cells may reflect a high-grade cancer located in the renal pelvis or ureter**, it is still necessary in such cases **to rule out a bladder lesion first**. This can be fairly efficiently performed by bladder barbotage that provides a good sampling of bladder epithelium with minimal contamination from the upper urinary tract.

Complete mapping of bladders with carcinoma in situ, as shown in Figure 23-22D, gives an excellent idea **of the spread of the lesion and often reveals foci of occult invasion**. For obvious reasons, such mapping is not possible in patients whose bladders have not been removed. The closest approximation to mapping is multiple mucosal biopsies **of the bladder epithelium** to localize the disease and define its extent. **The biopsies should be obtained with a cutting instrument that does not necessitate cauterization of the biopsy site**.

Besides biopsies of any visible, however trivial, abnormalities, multiple areas of the bladder must be sampled, at least:

- The trigone
- The anterior, posterior and lateral walls
- The dome
- In male patients, deep biopsies of the prostatic bed must be obtained to rule out extension of urothelial cancer into the prostatic ducts. This is of great clinical significance because such patients cannot be effectively treated by immunotherapy, unless the prostatic focus of disease is eradicated first.

Each biopsy should be submitted in a **separate, appropriately**

P.803

labeled bottle with fixative, in order to determine the distribution of the lesion and the location of occult invasion.

Figure 23-22 Urothelial carcinoma in situ. *A.* Voided urine. Small cancer cells with hyperchromatic nuclei and clean smear background are characteristic of this lesion (high magnification). *B.* Shows the histologic aspect of the extensive carcinoma in situ. In *C*, the gross appearance of the bladder shows areas of redness. *D.* The bladder was mapped showing several areas of carcinoma in situ extending beyond the area of redness, and also an extension of the tumor into the adjacent ureter. (Case courtesy of Dr. Myron R. Melamed, New York Medical College, Valhalla, NY.)

Laboratory Handling of Biopsies From Patients Suspected of Harboring Flat Carcinoma In Situ

Because the urothelium with a **carcinoma in situ** is often fragile and readily detached from the underlying stroma, it is important to ascertain **that all biopsy fragments are processed and examined**. DeBellis and Schumann (1986) proposed that **the liquid fixative** in which such biopsies are placed should be **processed by filtration (or cytocentrifuge)**, as it may often contain small fragments of cancerous epithelium or detached cancer cells. **The mere absence of the epithelium in a bladder biopsy should raise a suspicion of a carcinoma in situ**. A search must be initiated in multiple cuts of the biopsies for a few **residual attached cancer cells**, now recognized as the “**clinging form of carcinoma in situ**.”

As has been discussed in reference to the natural history of carcinoma of the bladder in industrial workers (see above), **the cytologic diagnosis of carcinoma in situ may remain unconfirmed for many years in the absence of an aggressive approach to bladder biopsies**. This has been repeatedly observed **in patients whose primary clinical problem is prostatic disease** and whose bladders did not receive the necessary attention. For further comments on the relationship of prostatic enlargement to bladder cancer, see comments on epidemiology of bladder cancer.

Invasive Nonpapillary Urothelial Carcinoma

In the cytologic preparation, there is usually evidence of **marked inflammation, bleeding, and necrosis**. In fully developed cancer, the predominant **cancer cells are of variable**

P.804

sizes, of irregular configuration, with scanty cytoplasm and prominent, obviously abnormal, hyperchromatic nuclei, similar to cancer cells observed in high-grade papillary tumors (see Figs. 23-14 and 23-21). Although most cancer cells have a basophilic cytoplasm, the presence of **single keratinized cancer cells with eosinophilic cytoplasm is not rare**. Sometimes, early invasive carcinoma may give a smear pattern **identical with carcinoma in situ**. In some advanced cancers with necrotic surface, the yield of cancer cells may be very low.

Figure 23-23 Urothelial carcinomas in situ. *A.* Various aspects of small cancer cells in the urinary sediment corresponding to the lesion shown in *B*. The images in *A* were generated by the Papnet device (with permission of TriPath Imaging, Burlington, NC). *C.* Another example of small cancer cells at high magnification in voided urine from a woman older than 30 years with multiple sclerosis and neurogenic bladder, corresponding to the lesion shown in *D*.

Histologic Variants of Urothelial Carcinoma***Squamous (Keratinizing) Carcinoma******Histology and Natural History***

The presence of a focal squamous component in urothelial carcinoma is a common finding.

Rarely, low-grade papillary tumors may have a squamous component (see Fig. 23-19B,C). Also, **condylomata acuminata** may be mistaken for squamous carcinoma in situ (see below).

Bladder cancers made up predominantly or exclusively of squamous (keratinizing) cell

types are less frequent in the Western world than urothelial carcinomas, although they are **common among patients with *Schistosoma hematobium* infestation** (see Chap. 22 and introductory remarks to this chapter). **It is generally assumed that such tumors originate from areas of squamous metaplasia or leukoplakia**, although this cannot always be conclusively documented. Squamous carcinomas, like urothelial carcinomas, may be **graded** according to the degree of differentiation (Koss, 1975). The very **well-differentiated grade I** variety, which may mimic **verrucous carcinomas** of other organs, is notorious for **local growth and late occurrence of metastases**. Patients with this type of bladder cancer, particularly common in the presence of *Schistosoma*, may **die of uremia** because of obstruction of the urinary tract by tumor.

Squamous cancers of higher grades are fully capable of metastases and may occur not only in the **bladder** but also in the **ureters** and the **renal pelves**.

Cytology

In most cases, the cytologic presentation of squamous carcinoma of the urothelium closely resembles similar lesions of the uterine cervix and bronchus (see Chaps. 12 and 20). The tumors shed **squamous cancer cells, some of bizarre configuration, with eosinophilic, often markedly keratinized cytoplasm. The nuclei are pyknotic** and occasionally may be totally submerged by keratin formation, with resulting formation of **“ghost” cells**, not unlike those observed in squamous carcinoma of the lung, described in Chapter 20 (Fig. 23-26). Clusters of cancer cells are common in bladder washings. Similar cells and tumor fragments may be observed in cell block preparations of urinary sediment.

P.805

Figure 23-24 Cytologic and histologic aspects of a carcinoma in situ with extension into the prostatic ducts. *A, B.* Show scattered small cancer cells with hyperchromatic nuclei. *C.* A representative section of the lesion of the bladder, which was shown by mapping to extend into the prostatic ducts, as shown in *D.*

Figure 23-25 Carcinoma in situ of bladder in characteristic cytologic presentation.

The voided urine sediment smears shown in *A-C* contained a fairly monotonous population of small cancer cells against a clean background. The histology of the lesion is shown in *D*.

P.806

In the **very rare squamous papillary urothelial tumors of low grade, concentrically arranged squamous cells or “squamous pearls”** may occasionally appear in urinary sediment (see Fig. 23-26B). **Condylomata acuminata of the bladder** may mimic the cytologic finding in squamous carcinoma (see below).

In cytologic material from **patients with *S. haematobium* infestation**, the presence of blood, pus, and necrotic debris may render the diagnosis of squamous bladder cancer very difficult. In fortuitous cases, **fragments of keratinized epithelium next to exceedingly well-differentiated squamous cancer cells** may be observed in the urinary sediment (Fig. 23-27). In a study performed at Memorial Hospital in New York City on urine sediments mailed in plastic bags from Bulawayo, Zimbabwe, the cytologic diagnosis of cancer could be rendered in only 15 of 29 patients with schistosomiasis and proved cancer of the bladder (Houston et al, 1966). Similar observations were made by Dimette (1955) and El-Bolkainy and Chu (1981).

Figure 23-26 Squamous carcinoma of bladder. *A-C.* Cytologic presentation of this tumor type in the urinary sediment. In *A*, the sediment shows mainly anucleated squames accompanied by a few squamous cells with essentially normal nuclear features. *B.* A “pearl” of squamous cancer cells. *C.* Dispersed squamous cancer cells in a background of massive inflammation. *D.* A squamous carcinoma of the urinary bladder, corresponding to *A-C*.

In women, the presence of squamous cancer cells in the sediment of voided urine may indicate the presence of a neoplastic lesion in the female genital tract. The uterine cervix, vagina, or vulva may be the source of such cells.

Adenocarcinoma

Histology and Natural History

Occasional **foci of glandular differentiation in urothelial carcinoma are common**. These focal changes cannot be recognized in cytologic samples. **Primary adenocarcinomas** may occur anywhere in the lower urinary tract, most commonly in the **bladder, but occasionally in the renal pelvis or the ureter**. **Risk factors** for adenocarcinoma of the lower urinary tract are: **extensive intestinal metaplasia, extrophic bladders** and the benign **villous adenoma, a polypoid lesion lined by intestinal epithelium, similar to lesions observed in the colon** (Koss, 1975; Grignon et al, 1991; Cheng et al, 1999; Oliva et al, 2002). Such tumors

P.807

may also arise in **cystitis glandularis** and **nephrogenic adenomas** (see Chap. 22 and below).

Figure 23-27 Squamous carcinoma of bladder in a patient with schistosomiasis. *A.* Massive inflammatory infiltrate is commonly seen in such patients. *B.* A “pearl” composed of squamous cells with nuclear atypia. *C.* Surface of a tumor composed mainly of anucleated squames. *D.* Wall of the bladder with invasive squamous carcinoma and ova of *Schistosoma hematobium*.

Adenocarcinomas of the urothelium are predominantly **of enteric type**. Most such **tumors closely resemble carcinomas of the colon and may be made up of columnar, mucus-producing cells or signet-ring type cancer cells**. The **signet-ring cell type** typically diffusely infiltrates the wall of the bladder, **resulting in a markedly thickened, rigid bladder wall, or leather-bottle bladder** (see Fig. 23-7D). Rarely, adenocarcinomas may present with **mucinuria, characterized by a viscous appearance of the urine**. **Adenocarcinoma in situ of the bladder has been observed** (see Fig. 23-29A,B) (Koss, 1975). The rarity of primary, uncomplicated adenocarcinoma in situ was recently emphasized by Chan and Epstein (2001).

Nazeer et al (1996) described an **adenocarcinoma in situ of endocervical type** developing in a case of a woman harboring endocervical type glands in the wall of the bladder.

Bladder adenocarcinomas of **clear cell type**, resembling vaginal lesions occurring in daughters of DES-exposed women (see Chap. 13), may occasionally be observed (Oliva et al, 2002) (see Fig. 23-29C, D). Amin et al (1994) described an exceedingly uncommon type of adenocarcinoma, **resembling ovarian serous carcinoma**, and named it micropapillary variant of urothelial carcinoma. The prognosis of urothelial adenocarcinoma is stage related but generally poor because metastases may occur early in the course of the disease.

Adenocarcinomas derived from the urachus (remnants of the embryonal omphaloenteric duct) arise in the **dome of the bladder and along the course of the urachus**, terminating at the umbilicus. These tumors have no specific histologic features that would permit their separation from other adenocarcinomas of the lower urinary tract. A patient reported by Hom et al (1990) had an adenocarcinoma with endocrine component.

Cytology

In fortuitous cases, adenocarcinomas can be recognized in the urinary sediment because they shed **cells resembling those of colonic carcinoma**. These are often **columnar in configuration and have large, hyperchromatic nuclei and vacuolated cytoplasm** (Fig. 23-28A,B). Such cells may form **clusters** that may show a **spherical or rosette-like arrangement** (Fig. 23-28C,D). We were fortunate to have observed a rare case of **enteric adenocarcinoma in situ of the bladder**. Numerous elongated or columnar cancer cells have been observed in the smear of the urinary sediment (Fig. 23-29A,B). The cells were very similar to those

P.808

of a fully developed adenocarcinoma, shown in Figure 23-28.

Figure 23-28 Adenocarcinomas of bladder. *A.* Columnar cancer cells with large hyperchromatic nuclei are representative of an adenocarcinoma, shown in *B.* *C.* A cluster of cancer cells, some of which at the periphery, have columnar configuration. *D.* The well differentiated adenocarcinoma corresponding to *C.*

Occasionally, **somewhat smaller and more spherical cancer cells, with large, peripheral nuclei and vacuolated, mucin-containing cytoplasm, resembling signet ring type cells of intestinal cancer**, may be observed. The presence of **very small signet ring cells in a woman may also indicate a metastatic mammary lobular carcinoma** (see below). Neither cell type can be differentiated from the cells of metastatic rectal or colonic adenocarcinoma discussed below (see Fig. 23-48). In many cases, however, **the sediment contains undifferentiated cancer cells and adenocarcinoma cannot be identified**. Occasionally, the **presence of mucin** may be observed in the background of the smears in the form of streaks of thick, eosinophilic precipitates. Reports of primary adenocarcinomas of the bladder by Trillo et al (1981) and DeMay and Grathwohl (1985) added no new information. Bardales et al (1998) reported a patient with **urachal adenocarcinoma** whose urinary sediment showed **bland columnar cells** and mucin.

In the rare cases of **clear-cell-type adenocarcinoma, papillary clusters of malignant cells with large nuclei, prominent nucleoli, and clear cytoplasm** may be observed (Fig. 23-

29C,D). Similar cases were reported by Peven and Hidvegi (1985) and Doria et al (1996).

Diagnosis of Urothelial Tumors in Special Situations

Lithiasis

As was described in Chapter 22, the urinary sediment in lithiasis may contain numerous papillary clusters of urothelial cells that may be mistaken for a low-grade papillary tumor. Occasionally, lithiasis may also cause some nuclear atypia of urothelial cells. However, **lithiasis is a risk factor and may conceal the presence of a high-grade urothelial carcinoma**. In the presence of lithiasis, the urinary sediment must be very carefully evaluated. In the presence of significant cellular abnormalities, a coexisting carcinoma must be ruled out.

Urothelial Carcinoma in Diverticula of the Bladder

Several cases of **urothelial carcinoma originating in outpouchings or diverticula of the bladder** have been observed in this laboratory (Fig. 23-30). The **cytologic presentation** of these lesions was identical to other urothelial cancers. However, the clinical localization of the lesions to a diverticulum proved to be difficult. It must be kept in mind that diverticula may have a very inconspicuous opening into the bladder, readily overlooked on cystoscopy.

P.809

Figure 23-29 Adenocarcinoma in situ. *A*, Tall, columnar cells with nuclear enlargement and hyperchromasia correspond to the tumor on the surface of the bladder shown in *B*. *C,D*, Clear cell adenocarcinoma. *C* shows clusters of small cancer cells with clear cytoplasm, corresponding to the tumor shown in *D*.

Carcinoma of the Bladder and Prostatic Disease

In situ and invasive carcinomas of the bladder may occur in patients with prostatic enlargement, caused either by prostatic carcinoma or hyperplasia (Barlebo and Sorensen, 1972; Mahadevia et al, 1986). In such cases, the cancer cells are those of urothelial

carcinomas, described above. The issue is discussed in the opening pages of this chapter.

UNCOMMON TUMOROUS CONDITIONS AND TUMORS OF THE BLADDER

Tumorous Conditions

Papillomatosis of Bladder

This is a rare disorder in which the entire surface of the bladder is covered with innumerable papillary fronds lined by essentially normal or minimally atypical urothelium. The condition is extremely difficult to treat conservatively and may require mucosal stripping or cystectomy (Lund, 1969). Little is known about the natural history of untreated papillomatosis (Koss, 1975). The lesion cannot be recognized cytologically.

Nephrogenic Adenoma (Adenosis of Bladder)

This uncommon lesion is composed of ducts and tubules, possibly of enteric origin (Koss, 1985, 1995). There are two reports suggesting that nephrogenic adenomas may be recognized in urinary sediment. Stilmant et al (1986) reported the presence of markedly abnormal cells in four patients. Three of the patients, however, had documented bladder cancer with carcinoma in situ. The cells shown in the illustrations could well have originated from the malignant epithelium. Troster et al (1986) observed papillary urothelial clusters in the urine of one patient. The clusters had no specific features. It is **doubtful that nephrogenic adenoma can be recognized in urinary sediment**. However, **adenocarcinomas may develop in such lesions** and may shed cancer cells (see above).

Endometriosis

Endometriosis of the lower urinary tract, particularly of the bladder, is a rare condition in young women that may cause symptoms similar to those caused by a tumor. Schneider et al (1980) reported clusters of **endometrial cells in voided urine** in a case of endometriosis of the bladder (Fig. 23-31A,B). There were some similarities between cells from endometriosis and metastatic endometrial carcinoma (Fig. 23-31C). Bohlmeier and Schroyer (1996), in reporting another case, pointed out that the endometrial cells in clusters in voided urine may be mistaken for cells of a urothelial carcinoma.

Figure 23-30 Carcinoma originating in bladder diverticulum. *A.* X-ray of bladder showing two diverticula, one of which contained a malignant tumor, shown in *C.* *B.* Composite picture of cancer cells from the voided urine sediment. *D.* Shows invasive carcinoma of bladder observed in the resected diverticulum shown in *C.*

Eosinophilic Granuloma

The disorder is discussed in Chapter 19. The rare eosinophilic granuloma may occur in the bladder or ureter. Because the lesion is subepithelial, there are no known specific cytologic findings.

Amyloidosis

Large deposits of amyloid in the wall of the bladder may elicit a granulomatous reaction with foreign body giant cells mimicking a tumor (Koss, 1975). There is no record of this diagnosis in either urine sediment or in direct aspirates of bladder wall.

Benign Tumors

Condylomata Acuminata

Condylomata acuminata may occasionally be observed in the urinary bladder (Koss, 1975). Petterson et al (1976) observed two such tumors in immunosuppressed patients following a renal transplant. With the passage of time, additional tumors of this type have been observed (summary in Del Mistro et al, 1988). **Condylomas of the bladder are often associated with condylomas of external genitalia, but may also occur as discrete tumors.** De Paepe et al (1990) observed several such incidental lesions **in women with urothelial cancer of the bladder.**

In a report from this laboratory, three patients with bladder condylomas were studied in depth (Del Mistro et al, 1988). By in situ hybridization, the **presence of HPV types 6 and 11** was documented. The tumors are very difficult to treat and have a marked tendency to recur. Follow-up information on one of the patients studied by Del Mistro et al, strongly suggested that the

lesion progressed to an invasive and metastatic squamous carcinoma of the bladder.

Progression of condylomata acuminata of the bladder to the verrucous variant of squamous carcinoma has been reported by several other observers (Walther et al, 1986; Tenti et al, 1996; Bruske et al, 1997; Botella et al, 2000). In the case described by Botella, HPV type 11 was documented in the condyloma and the subsequent carcinoma.

It is of note that the **DNA content of the bladder condylomas is aneuploid**, an observation confirmed by Cheng et al (2000).

Histology

The tumors, composed of folds of squamous epithelium, resemble genital condylomata acuminata, characterized by the presence of **koilocytes in the superficial epithelial layers**.

P.811

For a description of condylomas, see Chapter 11. In some tumors, marked **nuclear abnormalities** may be observed in epithelial cells (see Fig. 23-32D).

Figure 23-31 Endometriosis of bladder and metastatic endometrial carcinoma in bladder. *A.* Two clusters of small endometrial cells. *B.* Histologic section of bladder corresponding to *A* with an area of endometriosis. *C.* A small cluster of cells with vacuolated cytoplasm from an endometrial carcinoma, metastatic to bladder. (*A,B:* Courtesy of Dr. Volker Schneider, Freiburg I/B, Germany.)

Cytology

In voided urine, **koilocyte-like cells can be observed** (Fig. 23-32A). For a definition and description of koilocytes, see Chapter 11. **In a female patient, the possibility of origin of these cells in the uterine cervix must be ruled out. In male patients, such cells may originate in penile urethra** (see below). Hartveit et al (1992) reported the presence of koilocytes in the urinary sediment of numerous patients with a variety of bladder lesions but we were unable to duplicate this experience.

More importantly, perhaps, in two of our three patients, the urinary sediment contained **large**,

highly abnormal squamous cells with keratinized cytoplasm and large, hyperchromatic and pyknotic nuclei (Fig. 23-32B,C). "Cell-in-cell" arrangement was observed. Although in some of the cells perinuclear halos suggested a similarity to koilocytes, such cells were very **difficult to distinguish from cells of squamous carcinoma** (see Figs. 23-26 and 23-27). In the 3rd edition of this book, a lesion of the bladder with similar cytologic presentation was classified as "**squamous carcinoma in situ.**" The question of whether this lesion represented a flat condyloma of the bladder or, in fact, a squamous carcinoma cannot be resolved in the absence of HPV hybridization and follow-up information. Clearly, condylomata acuminata of the urinary bladder straddle the border between benign and malignant tumors, not unlike similar precancerous lesions of the uterine cervix (see Chap. 11 for further discussion of cervical lesions).

Squamous Papilloma of Bladder

Cheng et al (2000) described five squamous papillomas of the bladder and two of the urethra. The lesions failed to hybridize with HPV DNA and were diploid. These benign lesions are extremely rare and there is no information on their cytologic presentation.

Inverted Papilloma

An uncommon tumor of the urinary bladder, somewhat similar to a papilloma with a flat surface, was first described by Potts and Hirst in 1963. An uninterrupted layer of normal urothelium lines the surface of the tumor, which is made up of anastomosing strands of urothelium (Koss, 1975). The tumor is benign and there are **no known cytologic abnormalities associated with it.** An exceptional case of a malignant transformation of this tumor has been reported (Koss, 1985).

Villous Adenoma

Villous adenoma is a rare tumor of bladder of enteric origin that resembles similar tumors of the colon and rectum (Koss, 1975). There are **no known cell abnormalities in the urinary tract associated with this disorder.** Cheng et al (1999)

P.812

observed these uncommon tumors in the urachus, the dome, and the trigone of the bladder, and pointed out their **association with adenocarcinoma of the bladder** in 8 of 23 patients. Similar observations were reported by Seibel et al (2002). For discussion of cytologic findings in adenocarcinoma, see above.

Figure 23-32 Cytologic presentation of bladder condylomas in urinary sediment. *A* Typical koilocytes, a rather unusual finding. *B,C* Various aspects of markedly atypical squamous cells derived from condyloma shown in *D*. The cells seen in *B* and *C* could be readily interpreted as squamous cancer cells.

Tumors With Malignant Potential

Pheochromocytoma (Paraganglioma)

Histology and Clinical Presentation

These endocrine tumors, classically composed of **nests or cords of large, eosinophilic epithelial cells** (Zellballen), separated from each other by thin mantles of richly vascularized connective tissue, produce hormones, the **catecholamines**, that may cause episodes of paroxysmal hypertension on voiding. The serum levels of metabolites of catecholamines, such as vanilmandelic acid (VMA), are usually elevated and, combined with a history of “fainting in the bathroom,” a consequence of episodes of paroxysmal hypertension, will lead to the diagnosis. Most of these tumors are benign but malignant variants are known to occur (summary in Koss, 1975).

Cytology

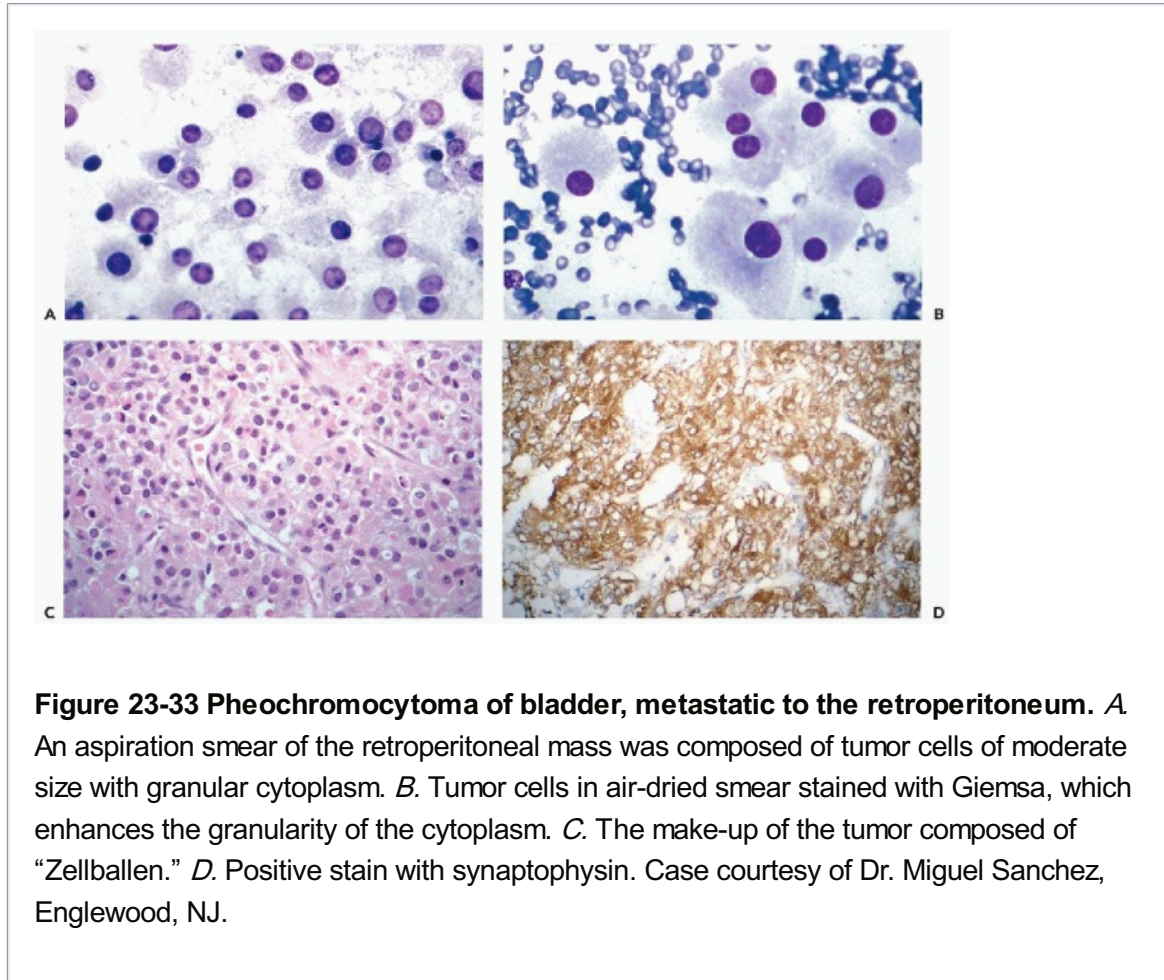

Because these tumors are located within the wall of the bladder, there are no recorded cases of tumor cells in voided urine. Through the courtesy of Dr. Miguel Sanchez, we examined an aspiration smear in a case of malignant pheochromocytoma of bladder, mimicking a retroperitoneal tumor. Clusters of **large cells with abundant eosinophilic, granular cytoplasm** and inconspicuous **spherical nuclei** were observed. As is common in endocrine tumors, **much larger cells with single or multiple hyperchromatic nuclei** were scattered among the mononucleated cells (Fig. 23-33).

Carcinoids

Carcinoids of the bladder are morphologically identical to similar tumors occurring in the

gastrointestinal tract and the lung and are composed of **sheets and ribbons of small cells, sometimes forming glands** (see Chaps. 20 and 24). Although usually benign, these tumors may display **malignant behavior**, as in the example cited by Koss (1985). There is no record of cytologic findings in bladder carcinoids but it may be assumed that the cytologic presentation would be similar to that of carcinoids in other organs, described in Chapters 20 and 24.

P.813

Malignant Tumors

Synchronous Carcinoma of the Bladder and Prostate (Uroprostatic Carcinoma)

Such tumors were recognized mainly in the European literature as “**transitional cell carcinomas of the prostate**” (Algaba et al, 1985), “**urothelial carcinomas in or of the prostate**” (Dhom and Mohr, 1977; Schujman et al, 1983; Goebbels et al, 1985). Dhom and Mohr, who reviewed the largest number of these cases, pointed out that when these tumors synchronously involved the bladder and the prostate, their prognosis was poor.

We observed three patients with this uncommon malignant tumor **that combined the features of primary bladder and prostate cancers**. In one of the patients, age 52, the disease was **first diagnosed on urinary sediment that indicated a high-grade urothelial cancer, which was confirmed by biopsy as a carcinoma in situ**. Subsequent biopsies of the enlarged prostate disclosed a **poorly differentiated malignant tumor** that combined with a **high level of prostate-specific antigen** in the serum, was considered to be a prostatic carcinoma and was treated with testosterone antagonists (Fig. 23-34). The patient died 2 years later with disseminated metastases. The outcome in the other two patients is not known as yet at the time

of this writing. Genega et al (2000) described an elaborate system of immunotyping to separate high-grade urothelial carcinomas from similar carcinomas of prostatic origin. It may well be that some of these tumors studied by Genega belong to the category of uroprostatic carcinomas.

Small-Cell (Oat Cell) Carcinomas

Small-cell carcinomas are either **pure**, composed of sheets and ribbons of small malignant cells akin to the oat cell carcinoma of the lung (see Chap. 20), or **mixed**, with either solid urothelial carcinomas or adenocarcinomas. The **endocrine features** of these tumors can be demonstrated either by immunomarkers or by electron microscopy (Cramer et al, 1981; Mills et al, 1987; Grignon et al, 1992). In some of these tumors, a **urothelial carcinoma in situ** can be documented, strongly suggesting that the tumors are variants of urothelial cancer (Koss, 1985). Some of these tumors may have ectopic hormonal activity (Partanen and Asikainen, 1985). These tumors have poor prognosis.

Cytology

Although **small-cell carcinomas** are uncommon, their cytology has been repeatedly described in recent years (van Hoesen and Artymyshyn, 1996;

P.814

Ali et al, 1997; Acs et al, 2000). The **tumor cells are small, about two or three times larger than normal lymphocytes, are usually of approximately equal sizes and appear singly or in small chains and clusters**, wherein **molding** of adjacent cells can be observed. The **cytoplasm is very scanty**, often not visible. The relatively large **nuclei show fine granularity. Nucleoli are absent or very small** (see Fig. 23-14D). In some cases, **larger cancer cells corresponding to urothelial carcinoma** can be present next to the small cancer cells. The differential diagnosis includes other malignant tumors composed of small cells, such as malignant lymphomas, which, however, rarely form organized clusters or show molding of adjacent cells. For further discussion of malignant lymphoma, see below.

Figure 23-34 Uroprostatic carcinoma. *A,B.* Urinary sediment contained a large number of small cancer cells, corresponding to carcinoma in situ shown in *C*. *D.* Shows a synchronous, poorly differentiated prostatic carcinoma that resulted in the patient's death

within two years.

Spindle and Giant Cell Carcinomas

These tumors are uncommon and there are few reported cases in the literature (Holtz et al, 1972). We observed one such tumor in the wall of a bladder diverticulum. Although the diagnosis of a malignant tumor can be easily established in the urinary sediment, the exact identification of such exceedingly rare tumors is rarely, if ever, possible. **Pseudosarcomatous spindly pattern** observed in urothelial cancer was illustrated in Figure 23-7C. A case of **carcinosarcoma**, arising in a bladder diverticulum, was reported by Omeroglu et al (2002).

Urothelial Carcinomas Mimicking Plasmacytomas

Sahin et al (1991) described an unusual **malignant urothelial tumor of the bladder mimicking multiple myeloma, wherein the tumor cells, aspirated from a skull metastasis, were similar to plasma cells**. A similar case was reported by Zhang et al (2002).

Mesodermal Mixed Tumors (Heterologous Carcinosarcomas)

These exceedingly rare variants of urothelial carcinomas of the urinary bladder closely **resemble similar tumors observed in the female genital tract** (see Chap. 17). In a case observed by us, the **urinary sediment contained a mixture of malignant cells**, some of which had **features of urothelial carcinoma** and others had features suggesting a chondrosarcoma (Fig. 23-35).

Lymphoepithelioma-Like Carcinoma

These exceedingly uncommon tumors of the bladder are similar to nasopharyngeal tumors, described in Chapter 21 (Dinney, 1993; Amin et al, 1994). There is no information on the cytologic presentation of these tumors.

Nested Variant of Urothelial Carcinoma

This is an uncommon type of urothelial cancer with insidious onset. The tumor is difficult to recognize in biopsies

P.815

because of its **deceptively benign presentation**: it is composed of nests and gland-like formations of urothelial cells that are approximately cuboidal and have only moderately enlarged, hyperchromatic nuclei (Talbert and Young, 1989; Murphy and Deana, 1992; Billerey et al, 1999). When recognized, the tumor is often deeply invasive and this most likely accounts for its poor prognosis. Volmar et al (2003) pointed out the similarity of these tumors to florid proliferation of Brunn's nests, discussed in Chapter 22. The nested carcinoma apparently is derived from surface epithelium that is only minimally atypical and does not show any evidence of carcinoma in situ or related lesions (Young and Oliva, 1966; recently confirmed by Dr. Victor Reuter, MSKCC, personal communication). It is therefore not surprising that **cytology** of these tumors is **non-diagnostic**. Cardillo et al (2003) examined 13 urine sediments from 7 patients and reported that in nearly all cases, the tumor cells could not be differentiated from normal urothelial cells. The observed changes consisted of only trivial nuclear abnormalities such as slight nuclear enlargement, irregular nuclear contour and slight hyperchromasia. Enlarged nucleoli were occasionally observed. The authors concluded that one should not attempt to

Figure 23-35 Mesodermal mixed tumor of bladder. *A.* The urinary sediment contained poorly differentiated cancer cells, corresponding to the mesodermal mixed tumor shown in *B.* In this area, the tumor was composed of poorly differentiated stroma and areas of cartilage. Elsewhere, the tumor contained elements of urothelial carcinoma that was in situ and invasive.

Sarcomas of the Bladder

These are mainly **rhabdomyosarcomas and leiomyosarcomas** (Koss, 1975) that occasionally shed cancer cells in urine. Krumerman and Katatikaru (1976) described a case of a **rhabdomyosarcoma** with intraepithelial spread in an adult. Generally, cells of sarcomas in the urinary sediment have malignant features, but usually cannot be accurately identified in the absence of prior histologic diagnosis or clinical history, including the age of the patient.

In children, **embryonal rhabdomyosarcomas (botryoid sarcomas)** of the vulva, vagina, prostate, and urinary bladder may occur. For an extensive discussion of these tumors, see Chapter 17. In Figure 23-36A,B, the cytologic findings in voided urine in a case of **botryoid embryonal rhabdomyosarcoma of bladder in a child** are illustrated. The small cancer cells have no distinguishing features and could not be further classified, except by comparison with histology. By contrast, spindly cancer cells of adult forms of rhabdomyosarcoma may show cytoplasmic striations (Fig. 23-36C,D).

A case of **primary angiosarcoma** of the bladder was reported by Schindler et al (1999) in an aspirated sample.

Malignant Lymphomas

Cells of the very rare primary malignant lymphoma of the urinary bladder cannot be differentiated from the cells of systemic tumors of the same type, involving the lower urinary tract (see below). A case of **synchronous lymphoma and adenocarcinoma** of bladder was described by Stitt and Colapinto (1966).

Primary Melanomas

Primary melanomas of the bladder are exceedingly rare. Khalbuss et al (2001) described such a case in an 82-year-old woman and summarized prior literature. In a personally observed case, the sediment of voided urine contained rare malignant cells with large nuclei and prominent

nucleoli, some containing brown melanin pigment in the cytoplasm. Phagocytized pigment was also observed in macrophages (Fig. 23-37).

Multiple Myeloma

Unusual primary carcinomas of bladder with cells mimicking plasma cells were mentioned above (Sahin et al, 1991; Zhang et al, 2002). We have not observed cells of a plasma cell myeloma in urinary sediment, although such cases were described by Auvigne et al (1956) and by Pringle et al (1974). However, **bizarre, multinucleated cells of renal tubular origin, a result of a so-called myeloma kidney**, may occur in the urinary sediment and are discussed below, in reference to voided urine cytology of the kidney.

Choriocarcinoma

Sporadic cases of primary choriocarcinoma of bladder in males have been reported (Weinberg, 1939). Such a case

P.816

was reported from this laboratory (Obe et al, 1983). The sediment of voided urine contained numerous malignant cells, most of which resembled cells of **urothelial carcinoma** but some that were **large and multinucleated, with large nuclei and nucleoli, consistent with syncytiotrophoblasts** (Fig. 23-38). The tumor and its cells gave a strongly positive reaction for human **chorionic gonadotropin**. Because the tumor was accompanied by a **flat urothelial carcinoma in situ**, it most probably represented an **unusual transformation of a urothelial carcinoma**. Yokoyama et al (1992) reported one case of primary and one case of metastatic choriocarcinoma in the bladder with similar findings. The primary tumor was also accompanied by a carcinoma in situ.

Tumors Most Likely Induced by Chemotherapy

Rare tumors of the urinary tract apparently induced by **cyclophosphamide** were discussed in Chapter 22.

TUMORS OF THE RENAL PELVES AND THE URETERS

Natural History and Pathology of Urothelial Tumors

Primary urothelial tumors of the renal pelves and ureters encompass the full scale of urothelial tumors described in the bladder and can be either **papillary or nonpapillary in type**. The most frequent clinical symptom is hematuria, sometimes associated with evidence of renal failure. These tumors may be unilateral or bilateral. The bilateral tumors may occur simultaneously or in sequence and create a major diagnostic and therapeutic dilemma. Four patients with bilateral renal pelvic carcinomas were observed by us over a period of 2 years.

In most patients, **carcinomas of the renal pelves or ureters are synchronous or metachronous with urothelial tumors of the bladder**. In a series of 41 patients with carcinoma of the renal pelvis and ureters, 50% of the patients developed bladder tumors (Kakizoe et al, 1980). Herr et al (1996) reported upper urinary tract tumors in 18 of 86 patients (21%) with primary bladder tumors followed for 15 years (median 7.3 years). In 5 patients, the tumors occurred 10 to 15 years after treatment of the primary bladder neoplasm. **The sequence of events cannot be anticipated** and the presence of tumors in one of these locations must automatically trigger the search for other tumors. These patients require long-term follow-up in which cytology of urinary sediment plays a major role (Smart, 1964; Sherwood, 1971; Koss, 1979, Herr et al, 1996). **Urothelial carcinoma in situ of distal ureters is a common finding in extensive, high-grade urothelial carcinomas of the bladder** (summary in Koss, 1975; Koss et al, 1977).

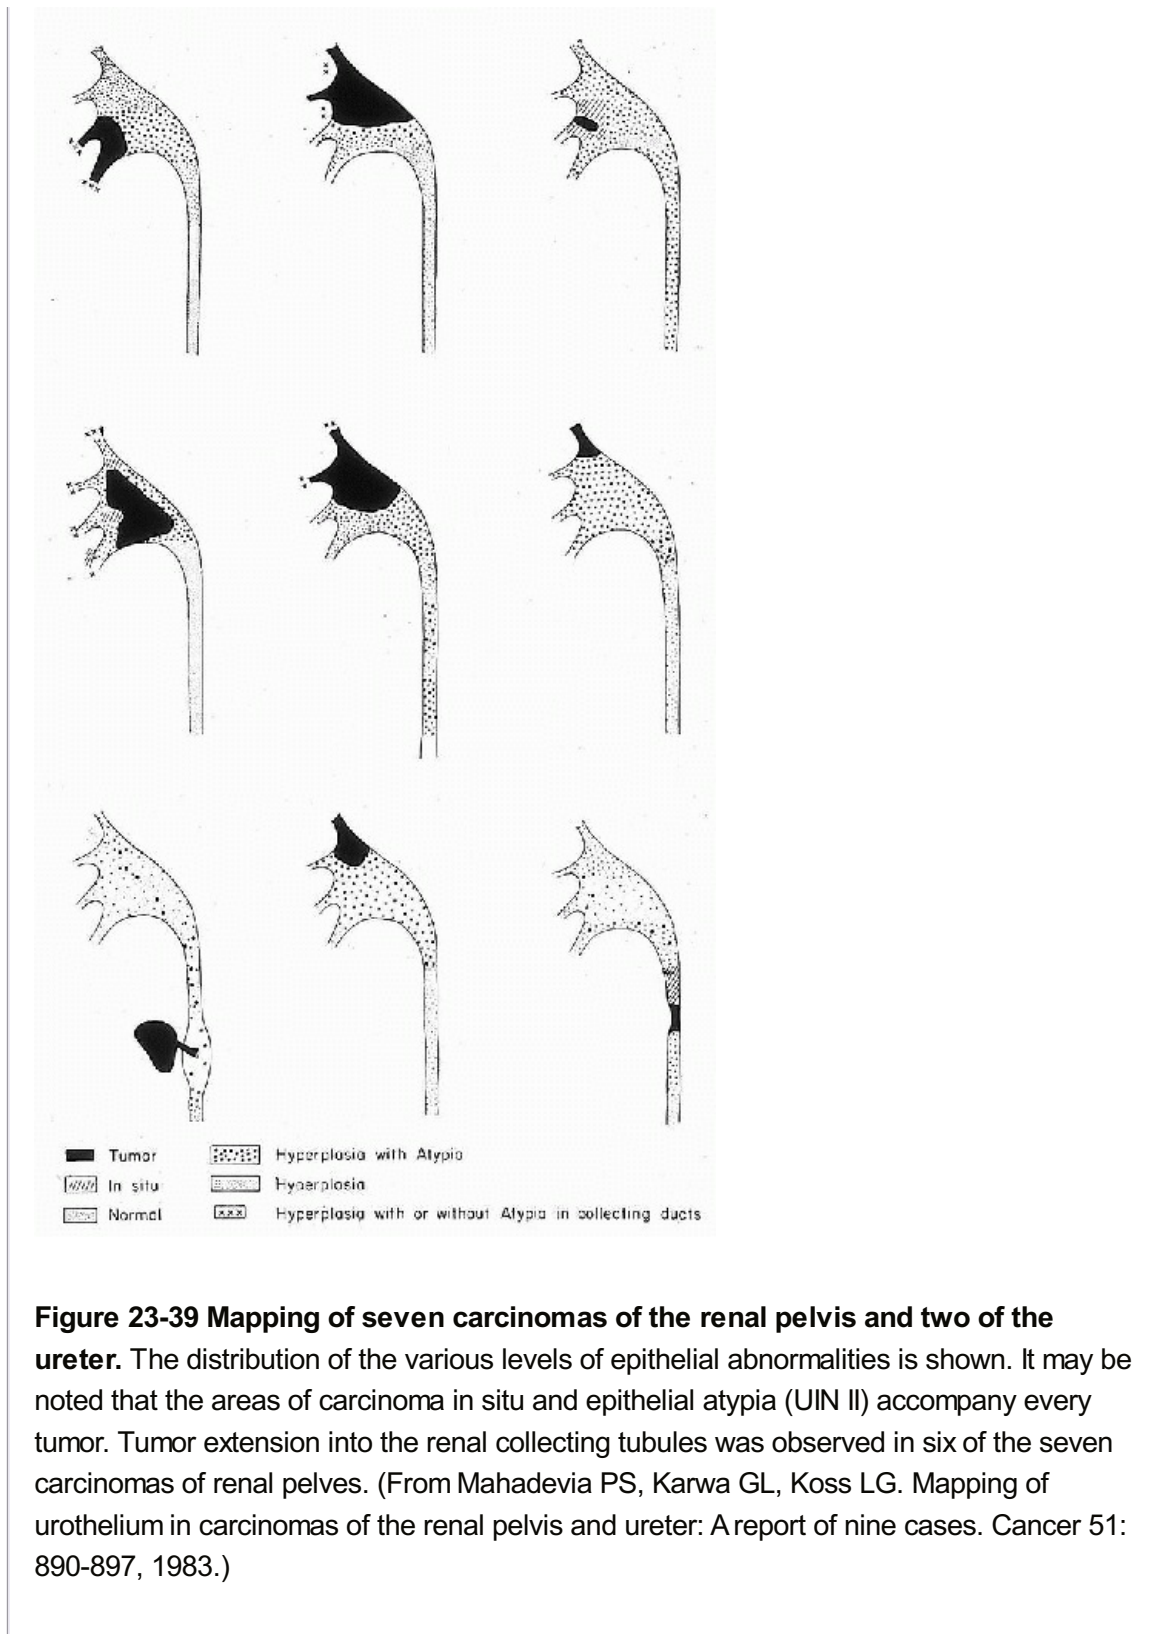

Primary urothelial carcinomas of the renal pelves and ureters have also been observed in **association with use and abuse of analgesic drugs containing phenacetin**. Although most of the reported cases originated in Scandinavian countries, sporadic observations on this association have been recorded in other countries as well (Johansson et al, 1974; Mihatsch, 1979; Lomax-Smith and Seymour, 1980). An important **corollary of phenacetin toxicity is papillary necrosis of renal cortex**, which occurs in more than half of the patients.

Carcinomas of the renal pelvis and ureters in patients receiving **cyclophosphamide** therapy have been recorded (see Chap. 22). It must be pointed out that the drug **busulfan** is capable of inducing major changes in renal pelvic epithelium that may mimic a carcinoma in situ (see Chap. 22 and Burry, 1974).

P.818

Mahadevia et al (1983) mapped seven high-grade urothelial carcinomas of the renal pelvis and two of the ureters and observed **peripheral atypical urothelium (dysplasia) in five patients and flat carcinoma in situ in four patients** (Fig. 23-39). Hence, it may be assumed that the sequence of events in renal pelvic and ureteral tumors is exactly the same as in the bladder. The findings were similar to the observations by Chasko et al (1981). **Extensive urothelial carcinoma in situ and related abnormalities were also observed in analgesic users** (Lomax-Smith and Seymour, 1980).

A few cases of **primary nonpapillary carcinoma in situ of the renal pelvis** diagnosed by cytology were recorded (Papanicolaou and Foote, 1949; Murphy et al, 1974; Stagier et al, 1980; Dodd et al, 1997). I have also observed one such case by courtesy of Dr. Harold Block of El Paso, Texas (see below).

Fromowitz et al (1981) reported from this laboratory on two cases of **inverted papillomas** of the ureter. **The report was in error** because one of the tumors recurred with features of urothelial carcinoma, grade II. The second patient developed an adenocarcinoma of bladder. As was stated in a subsequent publication (Koss, 1985), **papillary urothelial tumors of the ureter** may develop a flat surface, probably for anatomic reasons, and **mimic an inverted papilloma**. Such tumors may be the source of the occasional reports of positive cytologic findings in benign inverted papilloma.

Grading and Prognosis

The **grading** is identical with that of urothelial cancers of the bladder (see above). Large, high-grade tumors have a poor prognosis. Although renal pelvic carcinomas are theoretically fully curable by surgery if diagnosed early, the mortality in the Johansson's series of 62 patients (1974) was in excess of 50%. The results were not significantly improved in a more recent series of cases (Guinan et al, 1992; Herr et al, 1996). A major factor complicating cure by surgery is the occurrence of tumors elsewhere in the urinary tract.

The prognosis of urothelial tumors of renal pelvis or ureters depends primarily on **stage** of the disease, although tumor size and grade may play a role (Grabstald et al, 1971; Herr et al, 1996). Tumors invading through the wall of the renal pelvis or ureter have an ominous prognosis (Grabstald et al, 1971). The presence of carcinoma in situ in Mahadevia's study was of prognostic significance, inasmuch as two of four such patients developed metachronous carcinoma of the bladder, and one died of disseminated cancer. One of five patients with peripheral atypical urothelium also developed a tumor of the bladder. Weaver et al (2001) attempted to differentiate invasive from noninvasive urothelial carcinomas of the upper urinary tract by staining the cytologic samples with antibodies to CD 20 and CD 44 with uncertain results.

Adenocarcinoma and Carcinoid

Adenocarcinoma of the renal pelvis has been observed by us in a young woman with extensive **intestinal metaplasia of the renal pelvis and ureter**. **Mucinuria** may accompany such tumors. Sporadic cases of this tumor type have been reported in the literature (Bardales et al, 1998). A **carcinoid tumor** of renal pelvis was reported by Rudrick et al (1995).

Squamous Carcinoma

Sporadic cases of keratinizing squamous carcinoma of the renal pelvis have been recorded, sometimes in association with lithiasis of long-standing, causing **squamous metaplasia**. Several such cases have been reported in Japanese literature.

P.819

Cytology

As discussed at length in Chapter 22, **the principal purpose of cytologic examination of the upper urinary tract is to determine whether the space-occupying lesion is a tumor or a benign abnormality**. Most patients are symptomatic, often with gross **hematuria**. Radiologic examination, either as intravenous or retrograde pyelograms or computed tomography may disclose the location and the size of the lesion though, occasionally, no definite lesion can be identified. **The principal lesions that must be considered in the differential diagnosis are:**

- Tumors
- Stones
- Blood clots
- Very rarely, anatomic or vascular abnormalities

Heedless of the limitations of the method in low-grade papillary urothelial neoplasms, the urologists not familiar with the benefits of voided urine will often attempt to secure samples

by direct approach, either by brushings or by retrograde washings, barbotage, or by material obtained during ureteroscopy. Unless they are very skilled, many of the attempts at direct sampling will give unsatisfactory results. **Therefore, we strongly recommend that the first approach to the cytologic examination of the upper urinary tract should be by voided urine samples.** The methods were discussed in Chapter 22, where an analysis of cytologic findings is discussed according to the method of collection.

Figure 23-40 Renal pelvic carcinoma. *A,B.* The urinary sediment contained urothelial cancer cells of variable sizes corresponding to the pelvic tumor. *C.* Voided urine sediment (scanning power) containing small cancer cells corresponding to the tumor of renal pelvis shown in *D.*

Voided Urine

Cytologic presentation of **primary renal pelvic and ureteral urothelial tumors** is identical to tumors of the bladder (see above). Except for unusual conditions, discussed above, the **well-differentiated papillary urothelial tumors cannot be securely identified.** In high-grade urothelial carcinomas, the **population of malignant cells is sometimes surprisingly abundant** and readily identified (Fig. 23-40). The presence of a few **malignant cells of squamous type is common** in urothelial tumors. Such cells predominate in the rare **keratinizing carcinomas.**

In Mahadevia's study of **carcinomas of the renal pelves**, cited above, the urinary sediment disclosed **cancer cells in four of nine patients**, all with grade II or higher cancers. The sediment was considered **suspicious in three additional patients, atypical in one**, and was not examined in one.

Cytologic findings in a case of **adenocarcinoma of the renal pelvis** occurring in the **background of intestinal metaplasia**, were reported by Kobayashi et al (1985) and Yonekawa et al (2000). The findings suggested an adenocarcinoma because of the presence of clusters of cancer cells with **cytoplasmic vacuoles**, giving a positive stain for

mucin. **Mucinuria** may occur and may be recognized in smears of urinary sediment by thick, fibrillar eosinophilic background (Bardales et al, 1998).

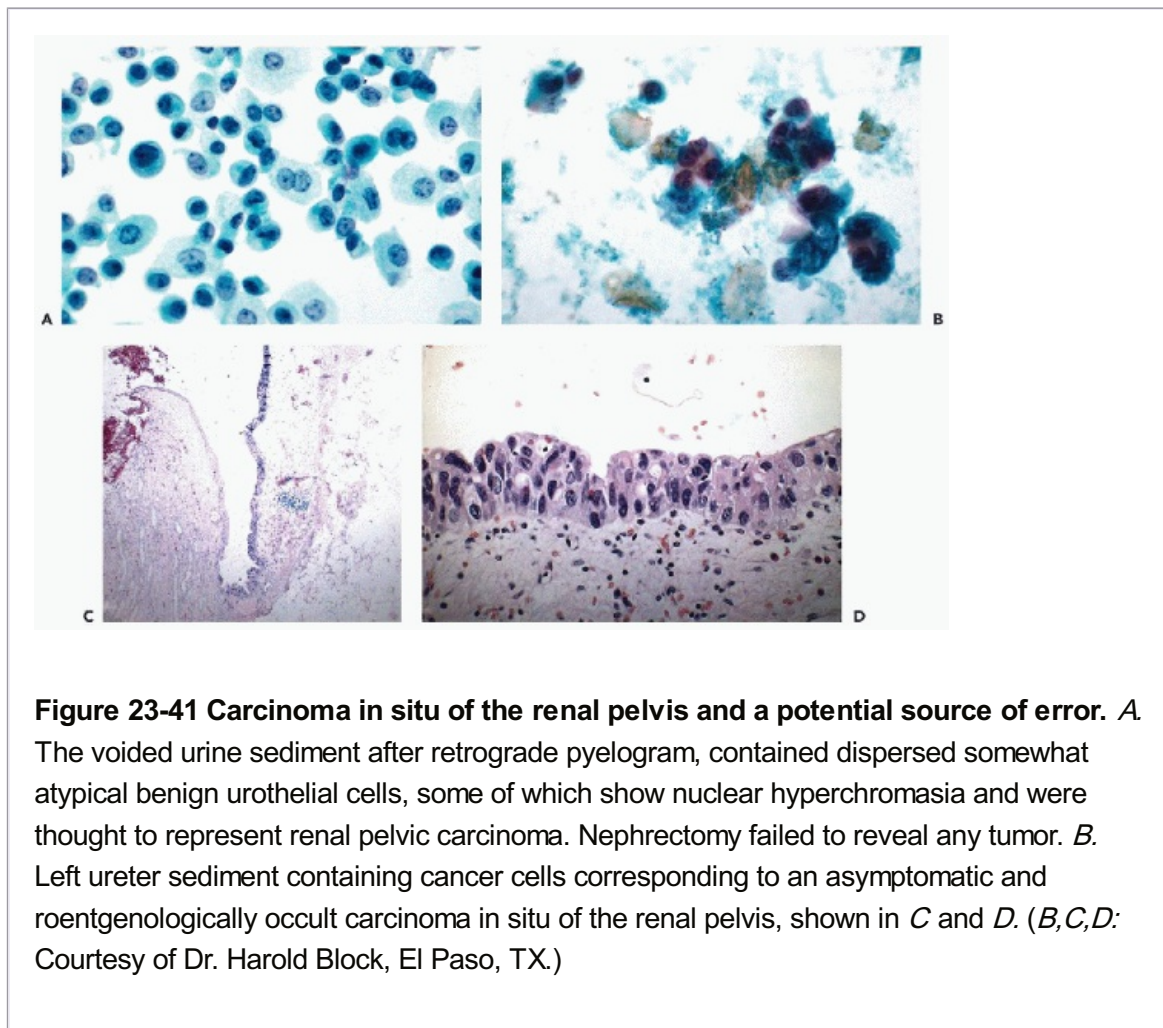

In a malignant **carcinoid tumor** of renal pelvis, polygonal malignant cells with large nuclei and occasional nucleoli were observed in urine by Rudrick et al (1995).

Other rare tumors of the renal pelvis, such as a **leiomyosarcoma** (Chow et al, 1994), were identified in fine-needle aspiration biopsies (FNA). See Chapter 40 for further comments on FNA of renal tumors.

Retrograde Catheterization

Cytologic examination of urine obtained by retrograde catheterization of ureters should be used for the purpose of localization of a high-grade tumor to either the left or right ureter or renal pelvis. Such events **are rare** and occur under the following conditions:

- The patient's voided urinary sediment contains unequivocal cancer cells, consistent with a high-grade tumor, and there is no evidence of a bladder lesion.
- The roentgenologic examination of the urinary tract is either negative or inconclusive.
- It is not clear whether the tumor is located in the left or right renal pelvis or ureter.

As an example, a **selective catheterization procedure** was applied to the diagnosis of an **occult carcinoma in situ of the right renal pelvis** in an 80-year-old woman with hematuria, absence of roentgenologic abnormalities, a negative cystoscopy, and with abundant evidence

of a high-grade carcinoma in voided urine (Fig. 23-41B-D).

As described in Chapter 22, **the urine specimens must be collected separately for each side** and great care must be exercised to avoid cross-contamination of the samples.

The cytologic findings are usually **complex because an abundant population of benign urothelial cells, occurring singly and in clusters, may obscure the presence of malignant cells** (see Chap. 22). Furthermore, perhaps as a result of multiple prior diagnostic procedures in some retrograde washings, the dispersed urothelial cells may show single cells with moderate nuclear hyperchromasia in the absence of tumor (Fig. 23-41A). Under these circumstances, great diagnostic caution is advised: the diagnosis of carcinoma should not be made unless the cytologic evidence is unequivocal.

Retrograde Brushing

Retrograde brushing is a method of direct sampling of the ureters, renal pelves, and renal calices that may be

P.821

performed under **radiologic control** or during **ureteroscopy** (endoscopic brushing). As is the case with retrograde irrigation material, **the samples are usually heavily contaminated with benign urothelial cells, occurring singly and in large clusters or clumps** that may cause significant problems of interpretation. In fact, in our consultation practice we have observed **more false-positive diagnoses of papillary tumors with this method of sampling than with other techniques. The diagnostic difficulties are increased if the sample contains somewhat atypical benign urothelial cells with enlarged nuclei, often the consequence of prior diagnostic procedures such as intravenous or retrograde pyelography** (see Fig. 23-41A). **The diagnosis of cancer can be rendered only in high-grade tumors and should be based on unequivocal evidence.**

Still, in skilled hands, the method offers the option of obtaining direct cytologic and tissue biopsy material for diagnosis (Gill et al, 1973). Bibbo et al (1974) reported excellent results with this method based on a small series of cases. Bian et al (1995) recognized in endoscopic brush specimens all high-grade malignant neoplasms of the renal pelves and suggested that the **smears are more informative than tiny tissue biopsies that can be obtained by this method.** Dodd et al (1997) compared endoscopic brush specimens with cytology of irrigation specimens and voided urine. Although these authors claimed that the brush cytology was a more specific and more sensitive sampling method, they **predictably failed to recognize seven low-grade papillary tumors. More importantly, however, Dodd et al failed to recognize four cases of flat carcinoma in situ that were diagnosed either in irrigation samples or in voided urine.** Zaman et al (1996) reported satisfactory diagnostic results with the brushing technique, which included **three renal carcinomas** (see below).

Figure 23-42 Examples of cytology of high grade renal pelvic carcinomas. Note the cellularity of the renal pelvic wash samples in *A* and *B* and renal pelvic brush specimen in *C* and *D*. Note the presence of mitoses in *D*. (*B*: High magnification.) *A* and *B*, same patient. *C* and *D*, each a different patient.

Personal experience confirms that cytologic samples obtained by retrograde brushing under fluoroscopic control may sometimes be informative and contribute in a major way to the diagnosis and localization of radiographically occult high-grade renal pelvic carcinoma (Fig. 23-42). **However, low-grade papillary tumors cannot reliably be detected by this technique.**

Ureteroscopic Biopsies

The technique of ureteroscopic biopsies of tumors of renal pelvis has been described (Tawfik et al, 1997). At the time of this writing (2004), the procedure is not widely used and it is not likely to replace cytology in the near future.

P.822

URINE FROM THE ILEAL CONDUIT (ILEAL BLADDER) OR OTHER ARTIFICIAL BLADDERS

Examination of urine from ileal bladders or other artificial bladders is a **mandatory follow-up procedure after radical cystectomy for urothelial tumors**. Cytologic findings in ileal bladder urine in the absence of cancer were discussed in Chapter 22. The recognition of cancer cells is not difficult because the cells are usually **larger than the cells from the ileal bladder and stand out because of large, hyperchromatic nuclei** (Fig. 22-43). **New primary cancers of the renal pelvis or of the ureters following cancer of the bladder may occasionally be diagnosed in this fashion** before there is clinical evidence of disease. Since hydronephrosis is a common complication in patients with ileal bladder, a radiographic examination may show only slight changes in the renal pelvis that could be readily overlooked, were it not for the cytologic report.

In one of our early patients, **sequential bilateral primary high-grade urothelial carcinomas**

of the renal pelvis were observed following radical cystectomy for cancer of the bladder. Both kidneys were removed, and the patient was maintained on dialysis for several months pending renal transplant. Several additional patients with carcinomas of renal pelvis or ureters following cystectomy for bladder cancer have been observed (Koss et al, 1977). Similar observations were reported by Malmgren et al (1971) and by Wolinska and Melamed (1973).

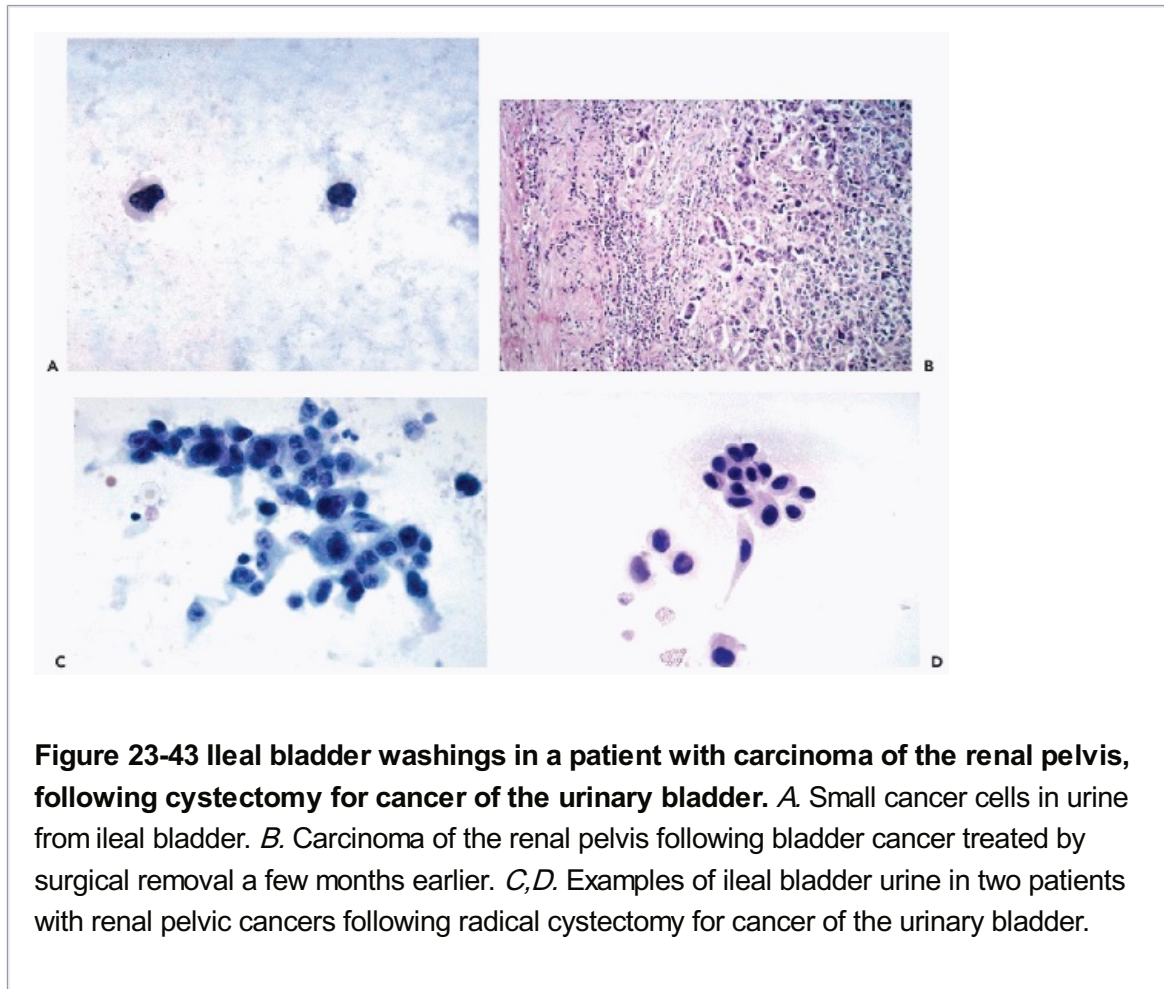

Figure 23-43 Ileal bladder washings in a patient with carcinoma of the renal pelvis, following cystectomy for cancer of the urinary bladder. *A.* Small cancer cells in urine from ileal bladder. *B.* Carcinoma of the renal pelvis following bladder cancer treated by surgical removal a few months earlier. *C,D.* Examples of ileal bladder urine in two patients with renal pelvic cancers following radical cystectomy for cancer of the urinary bladder.

On rare occasions, **primary cancers of urothelial type** may develop in the ileal bladder epithelium, adjacent to the stoma (Grabstald, 1974). The tumors may be in situ or invasive. Although the pathogenesis of this event is not clear, it may be hypothesized that the intestinal epithelium undergoes some type of metaplasia that may become malignant. We have observed two such cases.

TUMORS OF THE URETHRA

Benign Tumors

Condylomata Acuminata

The most common benign tumors of the urethra in both sexes are condylomata acuminata. As was repeatedly discussed

P.823

in the preceding pages, the tumors are associated with **human papillomavirus (HPV)**, most commonly the **types 6 and 11**, but occasionally also 16 and 18. In a series of urethral condylomas in young male patients studied in this laboratory, Del Mistro et al (1987) observed the lesion in 16 young adult patients and in one boy, aged 9, who had an occult lesion. By in

situ hybridization, **HPV types 6 and 11** were observed in 13 lesions, and **types 6 and 18** in one. In two lesions, only **type 11** was observed. One lesion and a recurrence thereof were negative with all probes. Four other recurrent lesions expressed the same type of viral DNA as the original lesion. Similar observations were reported in children (Vallejos et al, 1987).

In the female, condylomas of the urethra are usually visible lesions, associated with condylomas of external genitalia, a risk factor in cervical neoplastic events (see Chap. 11).

In the male, condylomas of the urethra occur in **two forms**: the **clinically evident lesions**, occupying the tip of the penile urethra at the meatus; and the **clinically occult lesions, located within the penile urethra**. The clinically obvious lesions are usually, but not always, associated with other genital condylomas. The frequency of occult lesions in the penile urethra is unknown, but there is concern that they may be the **source of infection of female partners** with HPV. They may also be **precursor lesions of squamous carcinomas of the male urethra**, which may also be associated with HPV infection (Malek et al, 1993). Giant penile condyloma of Buschke-Löwenthal, discussed in Chapter 11, is a closely related entity.

Histology

The visible papillary lesions are **identical with condylomas of the external female genitalia** (see Fig. 14-11A). The **condylomas of the penile urethra are generally flat lesions, mimicking cervical epithelial neoplasia (CIN) of low grade** and characterized by the presence of koilocytes in upper epithelial layers. Because of nuclear abnormalities, such as enlargement and hyperchromasia, which may be considerable, such lesions are readily **mistaken for a carcinoma in situ**, as became evident from several consultations. The association of condylomas with cancer of the bladder extending to the urethra was described by De Paepe et al (1990). Although the flat condylomas are benign by definition, and extremely unlikely to invade, all condylomas are difficult to treat because of a high rate of recurrence. See comments in Chapter 11 on new modes of treatment of condylomas.

Cytology

As in condylomas of the bladder, discussed above, **koilocytes** and **atypical squamous cells with enlarged, sometimes hyperchromatic nuclei** may be observed in voided urine sediments (see Fig. 23-32). In women, the cells may reflect a cervical or a vaginal lesion, but in the male, they usually indicate a lesion of the penile urethra or bladder. Cecchini et al (1988) performed **brushings of penile urethra** in 53 male partners of women with evidence of HPV infection (including CIN). Koilocytes were observed in smears of 26 (49%) of the men and none in the controls. Cecchini et al also performed colposcopy on the penile skin ("**penoscopy**") on the male partners. In 5 of them, subclinical lesions were observed. Giacomini et al (1989) also studied the penile urethra, using a specially designed swab.

Subclinical infection of the penile skin has been considered by some as a source of infection with HPV for women (Sedlacek et al, 1986; Barrasso et al, 1987). The penile skin lesions are generally inconspicuous, histologically unimpressive, and not amenable to cytologic examination. For further discussion of the possible clinical significance of these lesions in transmission of human papillomavirus between sexes, see Chapter 11.

Adenomatous Polyps of Prostatic Urethra

Uncommon benign exophytic **papillary tumors** of the male urethra, with **histologic and immunologic features of prostatic epithelium**, may be the cause of hematuria or dysuria

(Remick and Kumar, 1984; Chan et al, 1987). Schnadig et al (2000) described the cytologic findings in catheterized urine of several patients with this disorder. In some of these patients, **bland columnar cells** were observed.

Other Benign Tumors

Young et al (1996) described **urethral caruncles**, with markedly **atypical stroma, mimicking sarcomas or malignant lymphomas**. To our knowledge, these lesions have not been identified cytologically.

Malignant Tumors of the Female Urethra

De Paepe et al (1990) reported from our laboratories that the female **urethra was involved in 10 of 22 cases of bladder cancer**. The urethra may contain **urothelial carcinoma in situ, carcinoma in situ with extension to periurethral glands, or invasive cancer**. As an incidental finding in this study, 5 of 22 patients showed **condylomata of the urethra**.

Primary carcinomas of the female urethra are uncommon. Occasionally, the lesions occur in urethral diverticula. More than 80% of the lesions are **urothelial or squamous**, usually occurring in the anterior part of the urethra, whereas 20% are **adenocarcinomas of various types**, some originating in the glands of Littre (Grabstald, 1973; Sacks et al, 1975). Occasionally, **malignant melanomas** have been reported. There have been no known attempts to obtain routine smears of the urethra for purposes of early diagnosis of cancer. In fully developed cancer, the **voided urine** sediment may occasionally contain **cancer cells that reflect the type of the tumor**. Two examples of adenocarcinoma of the urethra are shown in Figure 23-44. One of them (Fig. 23-44C,D) originated in a diverticulum. Doria et al (1996) reported a similar case. In a case of **malignant melanoma of the urethra, we observed, in a direct smear, highly abnormal, but not diagnostic squamous cells, similar to cells observed in primary vaginal melanomas** (see Chap. 14).

Several personally observed patients with **treated squamous carcinoma of the distal (anterior) urethra were followed by direct smears of the treated area. Recurrent**

P.824

disease could be diagnosed in some of them while still in the stage of carcinoma in situ. **The cytologic presentation was similar to that of carcinoma in situ of the cervix or the vagina, rather than of the urinary bladder**. This is in keeping with the epithelium of origin, which in the distal urethra is of the stratified squamous and not the urothelial type.

Figure 23-44 Adenocarcinoma of female urethra in urinary sediment. *A,B.* Cancer cells, singly and in clusters, showing vacuolated cytoplasm and nucleoli. *C.* A papillary cluster of cancer cells typical of an adenocarcinoma. *D.* Adenocarcinoma of the urethra that developed in a diverticulum corresponding to *C.*

Malignant Tumors of the Male Urethra

Primary carcinomas of the male urethra not preceded by carcinoma of the bladder are exceedingly uncommon (Grabstald, 1973). However, **urothelial or squamous carcinomas of the prostatic portion of the male urethra may occur in about 10% of all patients after local treatment or radical cystectomy for carcinoma of the bladder** and, rarely, as a sequence of carcinoma of the prostatic ducts (Ritchie and Skinner, 1978). Penile discharge—mucoid, purulent, or hemorrhagic—may be observed on these occasions, and voided urine or washings of the urethra yield small cancer cells, singly or in clusters. Some of the observed lesions were carcinomas in situ or carcinomas in situ with superficial invasion (Fig. 23-45).

Primary malignant tumors of the anterior part of the male urethra are very rare. We observed several cases of **Paget's disease of the mucosa of the penile urethra and of the penile skin** in patients with metastatic urothelial carcinoma of the bladder (Koss, 1985). There is no known cytologic counterpart of these rare events.

Carcinoid

Sylora et al (1975) described a case of **malignant carcinoid** of the urethra with extensive metastases and carcinoid syndrome. There is no information on the cytologic presentation of this tumor. For comments on carcinoids of the bladder, see above.

Adenocarcinoma of Endometrial Type of Prostatic Utricle

These tumors, originating in **prostatic utricle** (uterus masculinus), although very rare, may have the clinical presentation of a urethral tumor (Melicow and Tannenbaum, 1971; Epstein and Woodruff, 1985). In one such personally observed case, there were **malignant cells in the urinary sediment and in the washings of the urethra** (Fig. 23-46). The tumor proved fatal

to the patient. Schnadig et al (2000) reported two such histologically confirmed cases, mimicking urethral polyps, with columnar cancer cells in catheterized urine. Masood et al (1991) reported a similar case, based on aspiration biopsy of the tumor. The presence of **grooved nuclei** was reported in the cancer cells.

P.825

(*A,B:* Oil immersion; *C:* High magnification.)

METASTATIC TUMORS TO THE BLADDER AND OTHER ORGANS OF THE LOWER URINARY TRACT

Malignant tumors originating in adjacent organs, and less often in distant sites, may metastasize to the bladder wall and rarely other organs of the lower urinary tract. Many of these metastatic tumors may be detected cytologically and their discovery may be of value to the attending physician in evaluation of the patient. **The presence of a metastatic cancer does not rule out the possibility of a simultaneous primary tumor in the lower urinary tract.**

Metastases From Cancers of Adjacent Organs

Uterine Cervix

Cells of squamous carcinomas of the uterine cervix may be observed in the urinary sediment, either as a consequence of **direct extension of the cervical tumor to the trigone of the bladder or because of metastases**. These cells are **identical to those observed in primary squamous cancer of the bladder** (see Fig 23-26). In a female patient, the possibility of cervix cancer must always be investigated. The same rule applies to the finding of **koilocytes or dyskaryotic (dysplastic) squamous cells**, as mentioned above. So far, we have not observed cells of metastatic endocervical adenocarcinoma in urinary sediment.

Endometrium

Metastatic endometrial carcinoma should be considered in the differential diagnosis of adenocarcinoma, if the urinary sediment in a **postmenopausal female patient** contains **small- or medium-sized, approximately spherical, cancer cells with glandular features**, particularly if forming spherical (papillary) clusters or rosettes. In most such cases, the adenocarcinoma is of primary origin, either in the bladder or in another organ of the lower urinary tract, and the endometrial origin of such cells is exceedingly rare. We have observed very few cases of endometrial carcinoma in the urinary sediment over the past 50 years (see Fig. 23-31C). Bardales et al (1998) reported one such case. On the rarest occasion, **synchronous bladder tumors and endometrial carcinoma** may be recognized in urinary sediment (see Chap. 17).

Ovary

We observed two instances of metastatic ovarian carcinoma to the urinary bladder. In one of the two cases, the cancer cells were remarkably large with huge nuclei and nucleoli (Fig. 23-47).

Colon

Cells of colorectal carcinoma are a relatively frequent finding in urinary sediment and may be the result of either **direct extension of rectal cancer to the urinary tract or metastases from a more distant portion of the bowel**. In most such instances, the cytologic diagnosis is possible, or at least should be considered. Rarely, the **large cancer cells may be of signet-ring type**. More often, they are of **columnar configuration, sometimes forming rosettes or parallel bundles (palisades)** (Fig. 23-48A,B). The columnar cells of metastatic colonic

carcinoma may be similar to cells of primary adenocarcinoma of the bladder (see Fig. 23-28). Koizumi and Schron (1997) pointed out that the **nuclei of metastatic colonic carcinoma may be pale and provided with large nucleoli, but this is very rarely seen in urinary sediment**. Occasionally, the finding of fecal material (plant cells) may lead to the diagnosis of a **vesicorectal fistula** that may be caused by rectal cancer.

Prostate

Cells of adenocarcinoma of the prostate may be occasionally observed in voided urine or in material obtained by prostatic massage. They are rather inconspicuous, usually small and difficult to identify in the absence of clinical data. Depending on the degree of differentiation of prostatic cancer, they are either **columnar, cuboidal, spherical, or oddly shaped**. The cells sometimes form papillary clusters but more often occur singly. The principal feature of these cells is the presence of **delicate cytoplasm and visible nucleoli**. Examples of cells of prostatic carcinoma in voided urine and other diagnostic media are shown in Chapter 33. A case of **prostatic duct carcinoma** diagnosed in urinary sediment was reported by Vandersteen et al (1997).

Metastatic Cancer From Distant Sites

Occasionally, carcinomas from more distant primary sites may be seen in the urinary sediment. An example of metastatic bronchogenic carcinoma is shown in Figure 23-48C,D. It is usually **not possible to determine on cytologic grounds, the origin of the primary tumor or for that matter, to determine whether the tumor is primary or metastatic**. There are two exceptions to this rule: **metastatic melanoma and tumors of the hematopoietic system**.

Metastatic Melanoma

Metastatic malignant melanoma may be recognized in the urinary sediment by the presence of pigment-containing malignant cells (Fig. 23-49A,B). In the absence of pigment or pertinent clinical history, the specific diagnosis can rarely be established. However, as pointed out by Piva and Koss (1964), even **the diagnosis of pigmented melanoma is not without its pitfalls. Pigment-containing renal tubular cells in cases of melanuria or pigmented macrophages may be mistaken for cells of the metastatic tumor (Fig. 23-49C,D). Unless clear-cut nuclear abnormalities, such as large nuclei with prominent nucleoli, are observed, the diagnosis of metastatic melanoma should not be made.** A case of metastatic melanoma with pigmented casts in the urinary sediment was described by Valente et al (1985).

Figure 23-47 Two examples of metastatic ovarian carcinoma to the urinary tract. *A.* A cluster of very large cancer cells with clear cytoplasm, corresponding to the ovarian tumor shown in *B.* *C.* Clusters of much smaller cancer cells corresponding to metastatic ovarian carcinoma in the ureter, shown in *D.*

Lymphomas and Leukemias

Malignant lymphomas may involve the urinary bladder and malignant cells may be identified in the urine sediment. As is usual in lymphoma, **the tumor cells lie singly, are approximately spherical, have usually scanty cytoplasm and show nuclear abnormalities such as grooves or clefts and the peculiar nuclear protrusions (nipples)** observed in effusions (see Chap. 26). Tanaka et al (1993) described a case of **Ki-1 malignant lymphoma** in urinary sediment. **The tumor cells in such rare cases may be very large and show abundant cytoplasm.** The differential diagnosis of Ki-1 lymphoma from metastatic carcinoma requires knowledge of clinical history and immunostaining.

Acute leukemias may sometimes begin with **hematuria. Blast cells may be identified in the urinary sediment** (Fig. 23-50A,B).

Multiple Myeloma

We have not observed cells of plasma cell myeloma in the urinary sediment. However, through the courtesy of Mr. Arthur Garutti, we observed a patient with renal impairment caused by multiple myeloma (**myeloma kidney**) who was shedding **bizarre multinucleated cells in his urinary sediment.** Undoubtedly, these cells **represented reactive renal tubular cells surrounding tubular casts of Bence-Jones protein, commonly observed in this disease** (Fig. 23-50C,D).

ACCURACY OF CYTOLOGIC DIAGNOSIS OF TUMORS OF THE LOWER URINARY TRACT

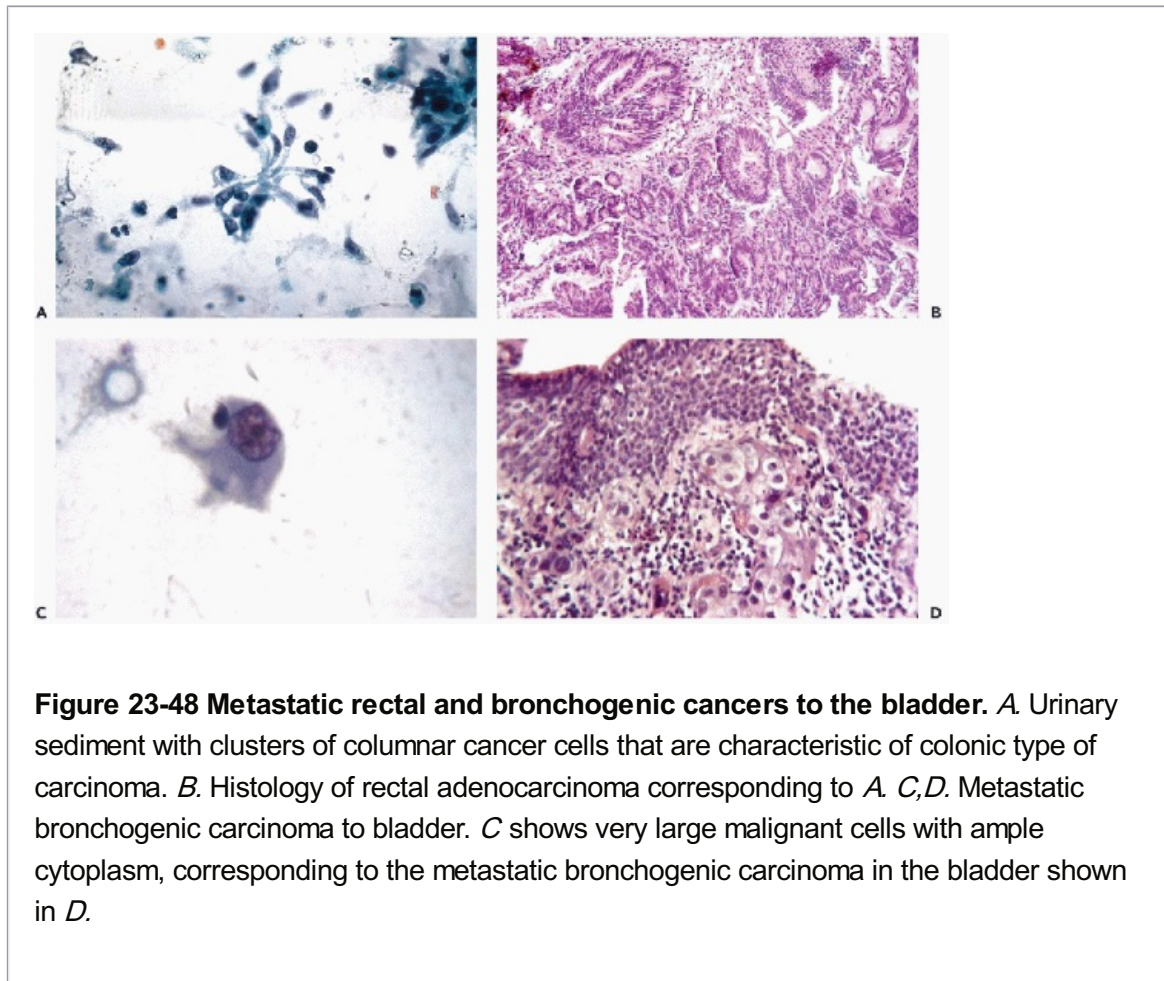

Bladder

The evaluation of the accuracy of urinary cytology **depends on the expectations of the**

observer. As was discussed above, it is totally unrealistic to expect that well-differentiated papillary urothelial tumors without obvious nuclear abnormalities (papillomas and low-grade papillary tumors) will yield diagnostic cells, either in voided urine or in specimens obtained by direct sampling (bladder washing or brushing). The rare exceptions to this rule were discussed above.

On the other hand, the **finding of clearly malignant cells in the urinary sediment or bladder washings calls for a major investigative effort, even in the absence of cystoscopic or radiographic abnormalities. Nonpapillary carcinoma in situ may be present in the bladder, ureter, or renal pelvis in the absence of localizing evidence, as documented in the preceding pages.**

P.828

The statistical evaluation of performance of urinary cytology published from various sources rarely reflect these elementary observations and thus result in **major confusion as to what urinary cytology can and cannot accomplish.** In experienced hands (Esposti and Zajicek, 1972), carcinoma of the bladder, grade II or above, was accurately identified in 78% of all cases. For high-grade tumors, the diagnostic accuracy reached 91%. None of the 52 cases diagnosed as papillomas and papillary carcinoma, grade I, could be identified cytologically. Morse and Melamed (1974) pointed out that the shedding of cancer cells in the voided urine is variable. Therefore, **three or more specimens must be examined for each patient.**

The results of a survey of the diagnostic efficacy of cytology of voided urine based on **three samples of voided urine** (Koss et al, 1985) is shown in Table 23-6. It may be noted that a

positive sediment observed in a single case of a papillary tumor grade I was subsequently shown to reflect a flat carcinoma in situ. The results in papillary tumors grade II closely reflected the distribution of the DNA values in this group of tumors with positive findings limited to aneuploid tumors (Tribukait, 1984; see below). Nearly all high-grade tumors were identified in the urinary sediment as malignant or suspicious.

Shenoy et al (1985) and Murphy (1990) claimed a high rate of cytologic diagnoses for grade I tumors although, subsequently, Murphy has reduced the expectations (Murphy, 2000). Several other recent analyses of performance of urinary cytology in reference to urothelial tumors were discussed above (Raab et al, 1994; Renshaw et al, 1996; Bastacky et al, 1999). In spite of elaborate methods of analysis, only high-grade tumors could be reliably identified in cytologic samples. These results were confirmed by Curry and Wojcik (2002).

Tumors of Renal Pelves and Ureters

Similar comments apply to **tumors of the renal pelves and ureters.** Eriksson and Johansson (1976), who studied 43 such patients, obtained positive cytologic results in 19 patients, all with tumors grade II or higher. In a subsequent group of poorly differentiated tumors, an accuracy of 71% was recorded. These observations were confirmed by Mahadevia et al (1983) who reported that urinary sediment cytology is an excellent diagnostic tool in the diagnosis of high-grade carcinomas of the renal pelves and ureters.

Several **important sources of cytologic error**, discussed

P.829

in Chapter 22 and the preceding pages, must be emphasized: **instrumentation, lithiasis, inflammation, infection with human polyomavirus, effects of drugs, and radiotherapy.**

Figure 23-49 Metastatic melanoma to bladder. *A.* Pigmented cancer cells in urinary sediment. *B.* Pigment-producing cancer in wall of bladder, corresponding to *A*. *C,D.* Another case of disseminated melanoma with extensive phagocytosis of the pigment in renal tubules. *C* shows one of the pigment-containing macrophages in urinary sediment. *D* shows section of the kidney obtained at autopsy, corresponding to *C*.

Is Cytologic Screening for Cancer of the Bladder Justified?

The most important accomplishment of cytology of the urinary tract is the diagnosis of **clinically unsuspected cases of carcinoma, particularly carcinoma in situ**. It has been documented above that this is indeed possible in screened industrial workers. There is considerable evidence that the salvage of such patients is potentially better than that of patients with advanced cancer, provided that treatment is applied before deep invasion or metastases occur.

The ultimate measure of success in a cancer detection endeavor is the extension of a good quality life for the patients. Unfortunately, as discussed above, the **survival rate of high-risk workers** who developed bladder cancer after exposure to *p*-aminodiphenyl was low. Because the study was conducted before contemporary methods of recognition and treatment of flat carcinoma in situ were available, most of these patients died with, or of the disease after a survival period of from 5 to 8 years. Although the follow-up of high-risk industrial workers has been a highly rewarding scientific exercise that clarified many points of natural history of bladder cancer, the direct benefit of these studies to the workers was not satisfactory. Similar doubts were expressed in the United Kingdom (Fox and White, 1976).

With the spread of understanding of the role played by carcinoma in situ and related lesions in the development of invasive cancer of the urinary tract, the issue of cancer detection may deserve another look. In this regard, it is important to note that Farrow et al (1977), by performing routine cytologic examination of voided urine on 3,500 patients (without cystoscopically visible lesions) who attended the urologic clinic at the Mayo Clinic, observed 69 documented cases (1.9%) of **carcinoma in situ of the bladder**. Holmquist (1988) observed **12 unsuspected bladder cancers in a survey of urinary sediments in 9,870 routine urinalysis samples** (1.2 per 1,000). In the Holmquist study, the initial wet preparations were followed by two routine cytologic procedures whenever there was some suspicion of abnormality. Thus, this is a hitherto unexplored source of case findings that is deserving of further study. In the absence of a large population survey, the actual benefits of bladder cancer detection to the society cannot be ascertained. More recently, Nickel et al (2002) observed three

P.830

cases of carcinoma in situ of bladder among 150 patients with "prostatitis" studied by voided urine cytology.

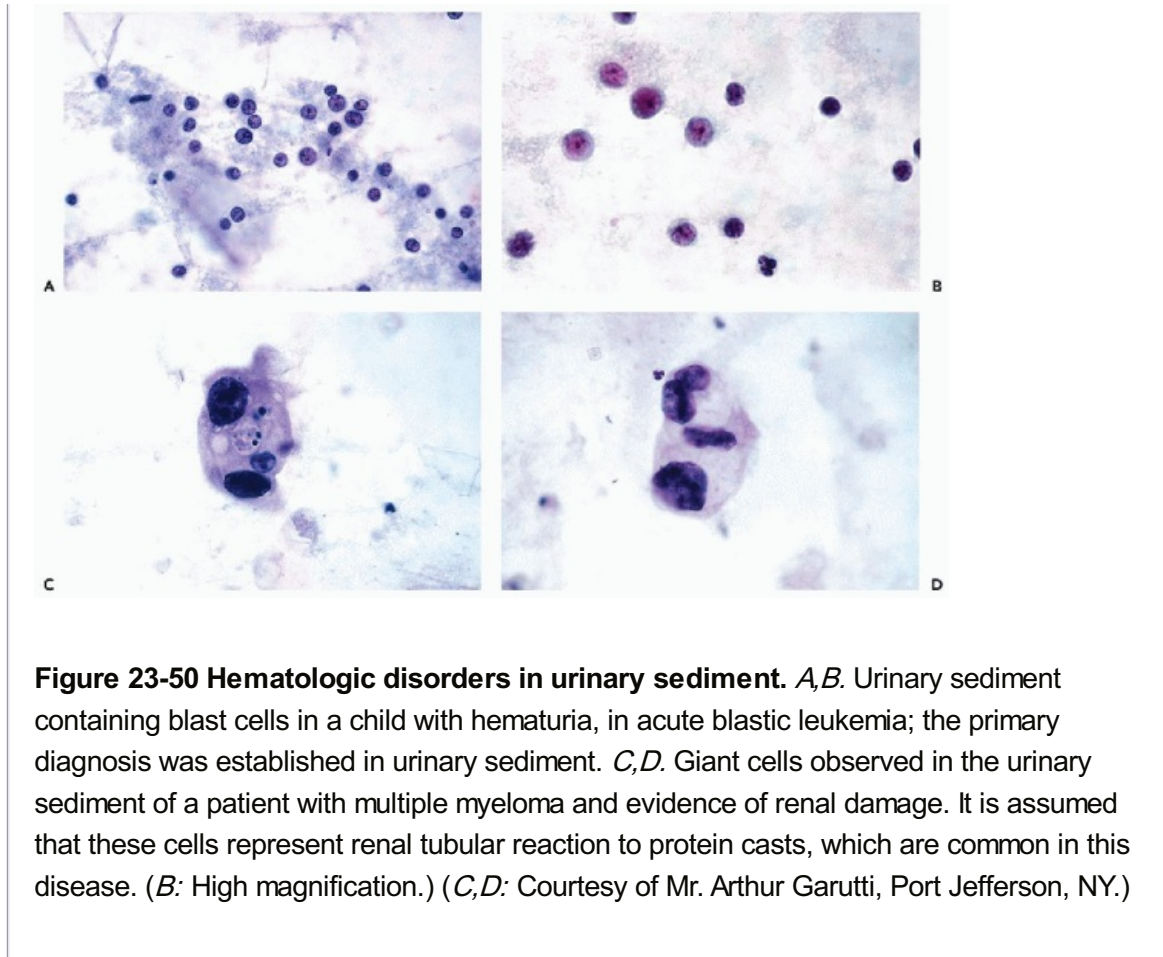

Figure 23-50 Hematologic disorders in urinary sediment. *A,B.* Urinary sediment containing blast cells in a child with hematuria, in acute blastic leukemia; the primary diagnosis was established in urinary sediment. *C,D.* Giant cells observed in the urinary sediment of a patient with multiple myeloma and evidence of renal damage. It is assumed that these cells represent renal tubular reaction to protein casts, which are common in this disease. (*B*: High magnification.) CYTOLOGIC MONITORING OF PATIENTS TREATED FOR TUMORS OF THE LOWER URINARY TRACT

The purpose of monitoring patients treated for tumors of the lower urinary tract is to detect tumor recurrence or formation of new tumors in a timely fashion. The **success of cytologic monitoring depends greatly on the type of tumor and the mode of therapy.**

Treatment Options and Their Impact

Surgical excision followed by cautery is still the therapeutic method of choice for primary and recurrent **superficial papillary bladder tumors**. **Tumors located in the renal pelvis may require nephrectomy.** This mode of treatment does not impede cytologic follow-up. **Radical cystectomy** with the creation of an ileal- or other type of artificial bladder, is curative of nearly all flat carcinomas in situ and some invasive tumors. Such patients should be monitored by **examination of urine from the artificial bladder** for the possible occurrence of a carcinoma of upper urinary tract.

Radiotherapy, either as a primary treatment mode or as an adjunct to surgical treatment of invasive tumors, poses a **special challenge** to cytologic follow-up because of radiation-induced cell changes in benign and malignant cells, discussed below.

Immunotherapy, with intravesical instillation of the **attenuated bovine tuberculosis bacillus (bacillus Calmette-Guérin; BCG)**, has become the treatment of choice for flat carcinoma in situ and related lesions of the **bladder** and has also been applied to urothelial tumors of the **renal pelvis**. Although the precise mechanism of effective treatment is still unknown, it is hypothesized that the inflammatory reaction attracts cytotoxic lymphocytes, which, in a manner

not clearly understood, helps in replacing diseased epithelium by normal mucosa.

A substantial number of papers based on randomized

P.831

trials have documented that, in some patients, long-term remissions and possibly cures of bladder lesions, can be achieved (Brosman, 1985; DeKernion et al, 1985; Pinsky et al, 1985; Herr et al, 1986; Guinan et al, 1987; Herr et al, 1989), but late recurrences of the tumors may occur (Herr et al, 1995). Although encouraging results for carcinoma in situ with prostatic extension were reported, still 10 of 23 such patients required cystectomy (Bretton et al, 1989). Similar data were reported by Cheng et al (2000). As described in Chapter 22, the treatment results in formation of **microscopic granulomas composed of epithelioid and giant cells of the Langhans' type in the wall of the bladder and in the adjacent prostate**, accompanied by a marked inflammatory reaction.

TABLE 23-6 COMPARISON OF HIGHEST CYTOLOGIC DIAGNOSIS IN THREE SPECIMENS OF VOIDED URINE WITH THE HIGHEST GRADE OF PRIMARY TUMOR IN THE NEAREST BIOPSY IN 203 EPISODES

Highest Histologic Diagnosis of Primary Tumor	No. of Cases	Highest Cytologic Diagnosis in 3 Specimens of Voided Urine	
		Negative or Atypical	Suspicious or Positive
Noninvasive papillary tumors	136	29 (22%)	107 (78%)
Grade I	6	5	1
Grade II	68	20	48
Grade III	62	4	58
Nonpapillary carcinoma in situ	14	0	14 (100%)
Invasive carcinoma (all grades)	27	2	25 (92%)
Carcinoma of ureter	4	0	4
Other cancers	2	1	1
No evidence of cancer	20	20	0
Total	203	52	151

(Koss LG, et al. Diagnostic value of cytology of voided urine. Acta Cytol 29:810-816,

1985, with permission)

Intravesical chemotherapy with instillation of cytotoxic drugs, mainly the alkylating agent thiotepa and the antibiotic mitomycin, have been used after resection of papillary tumors to reduce the frequency of recurrences, and also in the treatment of carcinoma in situ and resected high-grade tumors to prevent the occurrence of invasive carcinoma (summary in Soloway, 1983, 1985). Therapeutic successes have been reported (Soloway, 1985) but persuasive evidence that these treatment modes are equal or superior to BCG is not available.

Photodynamic therapy of carcinoma in situ and small papillary tumors after priming with hematoporphyrin derivatives has been reported (Hisazumi et al, 1984; Prout et al, 1987). The parenterally injected compound localizes in rapidly growing tissues, such as carcinomas, and renders them susceptible to phototherapy by laser. Similar attempts at treatment of carcinoma in situ of the bronchus, esophagus, and oral cavity have been attempted.

Cytologic Monitoring

Cytologic monitoring of patients treated for tumors of the lower urinary tract is effective only in early detection of new or recurrent high-grade tumors. Urinary tract cytology has so far not replaced cystoscopy in the follow-up and identification of new low-grade papillary bladder tumors. In the experience of this writer, the best **method of monitoring bladder tumors is by cytologic analysis of voided urine specimens. After radical cystectomy, the patients must be monitored by periodic cytologic examination of urine from the ileal bladder** (see above). As pointed out by Herr et al (1996), the monitoring may be required for **many years after treatment**. Patients **treated for carcinoma of the renal pelvis and ureter**, who are also prone to the development of new carcinomas elsewhere in the urinary tract, should also be monitored by urinary cytology.

Each monitoring sequence should be based on **three urine samples obtained on consecutive days** (see Chap. 22). **The presence of cancer cells, as described in the preceding pages, is always indicative of a recurrence or progression of urothelial carcinoma, regardless of the mode of treatment or presumed clinical status.** In fact, in several personally observed cases, urinary sediment that was positive for cancer cells, **in the presence of an apparently good clinical response to treatment**, anticipated an invasive or metastatic cancer that killed the patient. Harving et al (1988) documented that **cytologic analysis is more sensitive than multiple biopsies** in predicting tumor recurrence or progression. The need for cytologic monitoring was also emphasized by Hopkins et al (1983), who pointed out that **patients with seemingly innocuous low-grade**

P.832

tumors may develop an unexpected invasive cancer of the bladder, presumably derived from adjacent carcinoma in situ and related lesions.

Figure 23-51 Radiation failure. Two examples of residual carcinoma in situ in patients whose invasive tumor was eradicated by radiotherapy.

None of the cytotoxic drugs or BCG causes epithelial cell changes that could be confused with cancer. Although minor atypias in the form of cellular and nuclear enlargement may be observed with thiotepa, neither mitomycin nor BCG causes any significant cytologic abnormalities, except for granulomatous inflammation in BCG. The granulomas may be observed in the urinary sediment, as described in Chapter 22.

Monitoring of **patients undergoing radiotherapy** is difficult because of radiation changes affecting **benign epithelial cells**, as discussed in Chapter 22. Radiotherapy of carcinomas of the bladder may cause **nuclear pyknosis and ballooning of the tumor cells**, a change often reflected in smears of urinary sediment. The degree of nuclear abnormality in the cancer cells usually, but not always, allows a differentiation between the irradiated benign and the irradiated malignant cells. However, when the nuclei of irradiated benign cells show nuclear hyperchromasia, the differential diagnosis becomes difficult. In such situations, it is advisable to **withhold judgment until clear-cut evidence of cancer is obtained on subsequent samples of urine. The cells of bladder cancer recurring after radiotherapy are in no way different from the cells of the primary tumor.** Numerous biopsies or cystotomy often may be required to obtain histologic confirmation of a tumor, especially if there is considerable scarring of the bladder wall.

Cytologic studies of urinary sediment proved to be quite useful in following a group of patients with bladder cancer treated by radiation before undergoing surgery. If preliminary radiotherapy was successful, it resulted in rapid diminution in the numbers of cancer cells, and in four cases, in complete disappearance of cancer cells. In these latter cases, histologic studies of totally removed bladders failed to reveal the presence of cancer. However, **in several cases of carcinoma of the bladder, the urinary sediment remained positive in spite of a very favorable clinical response of the invasive tumor to radiotherapy. Subsequent surgical removal of the bladder revealed residual carcinoma in situ that apparently did not respond to radiation treatment, whereas the invasive tumor was obliterated** (Fig. 23-51). Similar observations were made with carcinoma of the cervix (see Chap. 18) and in carcinoma of the esophagus (see Chap. 24).

As emphasized above, the cytologic approach to monitoring of treated patients will fail in discovering new or recurrent low-grade papillary tumors. This fundamental fact has led to the development of a substantial number of new methods of monitoring of bladder tumors.

Monitoring of Tumors of the Lower Urinary Tract by Methods Other Than Cytology

DNA Ploidy Analysis

It has been known since the publications by Falor (1971), Falor and Ward (1973, 1976) and Granberg-Ohman et al (1984), that most **low-grade noninvasive bladder tumors had a chromosomal component in the normal diploid range and that high-grade tumors had grossly aneuploid karyotypes**. With the development of methods of **DNA quantification** by cytophotometry, image cytophotometry, and flow cytometry, enumeration of chromosomes could be replaced, to some degree, by measurements of DNA in cell populations. The methods, their accomplishments, and limitations, are described in Chapters 46 and 47.

The initial studies of **DNA content of bladder tumor cells**, conducted by **cytophotometry**, confirmed that low-grade papillary tumors are, for the most part, in the diploid range (i.e., have a DNA content identical or similar to normal tissues). With increasing grade, there was an increasing degree of abnormalities, reaching high aneuploid values for high-grade tumors (Lederer et al, 1972). With the developments in **flow cytometry**, rapid DNA measurements could be performed in a large number of bladder tumors (Fig. 23-52A). As was shown by Wijkstrøm et al (1984), the DNA values obtained by flow cytometry compared favorably with cytogenetic analysis.

Notable contributions to flow cytometric DNA studies of **bladder tumors** were made, among others, by Tribukait,

P.833

whose large experience is summarized in Table 23-7. It may be noted that DNA analysis confirms cytogenetic findings, inasmuch as **most noninvasive low-grade tumors have a DNA content in the diploid range. Tumors grade II are almost equally divided into diploid and aneuploid categories**, reflecting cytologic findings shown in Table 23-6. **Tumors grade III and all cases of flat carcinoma in situ (Tis) are aneuploid, confirming the clinical and pathologic observations on the origin of most high-grade invasive cancers of the urinary bladder from carcinomas in situ.** The analysis by stage also confirmed that most **deeply invasive bladder tumors were aneuploid**.

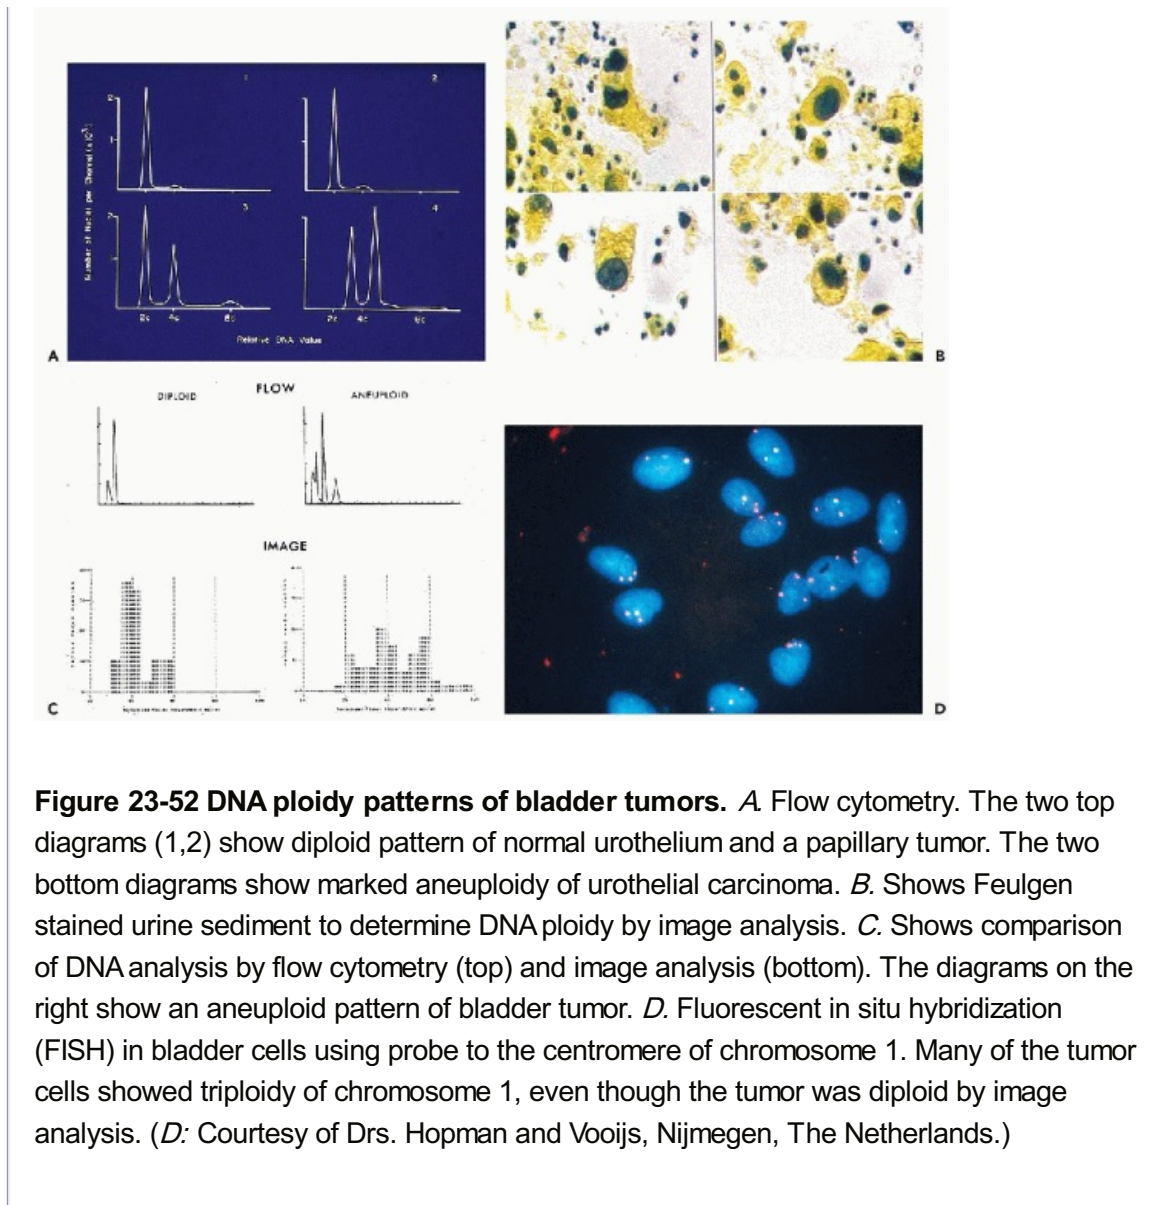

Figure 23-52 DNA ploidy patterns of bladder tumors. *A.* Flow cytometry. The two top diagrams (1,2) show diploid pattern of normal urothelium and a papillary tumor. The two bottom diagrams show marked aneuploidy of urothelial carcinoma. *B.* Shows Feulgen stained urine sediment to determine DNA ploidy by image analysis. *C.* Shows comparison of DNA analysis by flow cytometry (top) and image analysis (bottom). The diagrams on the right show an aneuploid pattern of bladder tumor. *D.* Fluorescent in situ hybridization (FISH) in bladder cells using probe to the centromere of chromosome 1. Many of the tumor cells showed triploidy of chromosome 1, even though the tumor was diploid by image analysis. (*D*: Courtesy of Drs. Hopman and Vooijs, Nijmegen, The Netherlands.)

DNA Content of Bladder Washings (Barbotage)

Given the premise that the **DNA content of the epithelium of the bladder may be predictive of future behavior and, thereby, the prognosis of bladder tumors**, DNA measurements on bladder washings were initiated by Melamed et al (1976). A large number of papers from the Memorial-Sloan Kettering Cancer Center suggested that aneuploid DNA content of the cells in suspension, obtained either at the time of cystoscopy or by catheter (barbotage), was predictive of tumor persistence, recurrence, or impending invasion (Klein et al, 1982; Badalament et al, 1986, 1987, 1988). The method was shown to be particularly **effective in monitoring patients with carcinomas in situ undergoing treatment**.

Unfortunately, as is discussed in Chapter 47, although histograms that are clearly normal or abnormal are easy to interpret, many of the histograms obtained from bladder washings, particularly from patients with low-grade tumors, are not clear-cut, difficult to interpret, and require artificial classification schemes (Koss et al, 1989). Synchronous studies

P.834

of the DNA content by image analysis and flow cytometry disclosed that some samples, which were considered normal (diploid) by flow cytometry, could contain small aneuploid cell populations that were revealed by image analysis and were of predictive value for tumor

recurrence or progression (Koss et al, 1989). The method proved **unsatisfactory in attempting to predict recurrences of low-grade papillary tumors**, as is the case with conventional cytology. Attempts to replace bladder washings or barbotage with **samples of voided urine for flow cytometric analysis of DNA**, as suggested by deVere White et al (1988), **were not successful** in our hands.

TABLE 23-7 DISTRIBUTION OF DNA VALUES IN 277 UNTREATED BLADDER TUMORS

Grade	No. in Group	Diploid	Aneuploid*
Distribution by Grade			
0	2	2	0
I	30 (100%)	24 (80%)	6 (20%)
II	107 (100%)	56 (52%)	51 (48%)
III	130 (100%)	6 (5%)	124 (95%)
Adenocarcinoma	8	1	7
Total	277	89	188
Distribution by Stage			
T ₀	42 (100%)	32 (76%)	10 (24%)
T ₁	118 (100%)	50 (42%)	68 (58%)
T _{2,3,4}	93 (100%)	7 (7.5%)	86 (92.5%)
Tis†	24 (100%)	0	24 (100%)
TOTAL	277	89	188

* Includes tetraploid-aneuploid tumors.

† Tis, flat carcinoma in situ.

(Modified from Tribukait B. Flow cytometry in surgical pathology and cytology of the genito-urinary tract. Koss LG, Coleman DV (eds.) Advances in Clinical Cytology. New York, Masson Publishing, 1984: pp 163-189.)

Image Analysis

The principles of image analysis of cells are discussed in Chapter 46. For a number of years, our group has attempted to develop a system of objective, computer-based analysis of urothelial cells in voided urine sediments processed by the method of Bales, described in Chapter 44. The initial results indicated that several subgroups of urothelial cells could be identified with accuracy surpassing that of the human observer (Sherman et al, 1986). Furthermore, as discussed above, the “atypical” urothelial cells could be classified into two groups of diagnostic value. Automated processing of 119 specimens of voided urine yielded promising results (Sherman et al, 1984). However, subsequent studies revealed errors in the evaluation system that could not be corrected without a major improvement in the image capture and computer systems.

Work with an apparatus known as Papnet System, based on capture and selection of cell images by a neural network, proved to be interesting. The apparatus was capable of identifying cancer cells in smears of the urinary sediment, whether prepared by conventional methods or processed as a liquid sample (Hoda et al, 1995). An example of the Papnet display of the urinary sediment in bladder cancer is shown in Figure 23-23A.

An interesting approach to the laboratory **processing of “atypical” or “suspicious” smears** of urinary sediment was proposed by Dr. Jay Amberson (Dianon Systems, Inc., Stratford, CT). In such cases, a duplicate smear is stained with **Feulgen stain** and the **DNA profile** is established by rapid image analysis. In Feulgen-stained smears, cancer cells are easily recognized (Fig. 23-52B). If the DNA profile shows abnormal distribution of DNA (Fig. 23-52C), the urologist is informed of the possibility of a malignant lesion. Unfortunately, a full evaluation of the clinical benefits of this technique is not available at the time of this writing (2004). Wojcik et al (2001) adopted **laser scanning cytometry** for evaluation of DNA ploidy in urinary sediment and reported excellent results in recognition of malignant tumors. The same author pointed out that superficial umbrella cells may be a **source of abnormal ploidy** and, thus, should be excluded from measurements.

It is not likely that in the near future, quantitative image analysis will replace visual examination of cells in the urinary sediment, although the Feulgen technique is interesting and clearly deserving of further investigations.

Morphometry

A number of investigators, particularly a Dutch group headed by Baak, have advocated morphometric measurements

P.835

of cellular and nuclear features **in histologic sections of bladder tumors** as a predictor of prognosis (Blomjous et al, 1989). The method is based on subjective selection of the microscopic field to be measured. To our knowledge, the method has not been applied to cytology of the urinary sediment.

New Technological Developments

Monoclonal Antibodies

Numerous monoclonal antibodies have been tested or are being developed as specific markers for the identification of bladder tumors with invasive potential (Cordon-Cardo et al, 1990; Fradet

et al, 1984, 1986, 1987). Some of these monoclonal antibodies may be used in conjunction with flow cytometry to identify subpopulations of cells with particular characteristics and measure their DNA content. Other markers used for these purposes are monoclonal antibodies to keratin filaments, which facilitate the selection of epithelial cells from all other cells in bladder washings. In such studies, the DNA can be measured in epithelial cells only (Ramaekers et al, 1984, 1986). A commercially available test ImmunoCyt (Diagnocure, Saint-Foy, Quebec, Canada) has been reported to have better specificity and sensitivity for **detection of low-grade, low-stage tumors of the bladder** than conventional cytology (Fradet et al, 1997; Mian et al, 1999).

Nuclear Matrix Proteins

Keesee et al (1996) explored the possibility that the nuclear matrix proteins may show sufficient differences between normal and cancer cells to apply this system to bladder cancer detection and diagnosis. A test kit NMP22 (Matritech Corp., Newton, MA) was tested by a number of investigators (Soloway et al, 1996; Stampfer et al, 1998; Zippe et al, 1999) with interesting results, particularly in reference to low-grade papillary tumors. Del Nero et al (1999) reported a high sensitivity but also a high rate of false-positive results with this method.

Bladder Tumor Antigen

Bard bladder tumor antigen test, BTA stat, (Bard Diagnostics, Redmond, WA) is a latex agglutination assay for qualitative detection of basement membrane antigen in urine. Several investigators reported good specificity and sensitivity of this test when compared with urine cytology (Sarosdy et al, 1995; Leyh et al, 1997; Murphy et al, 1997; Sharma et al, 1999). Ramakumar et al (1999) observed that the test had high sensitivity, when compared with several other objective laboratory tests, particularly **telomerase activity** (Lin et al, 1996; Kyo et al, 1997).

Telomerase Activity

Telomerase, an enzyme that is essential for maintenance of chromosomal integrity, can be measured in urine by polymerase chain reaction (PCR) with appropriate primers. It has been reported that the method is more specific than any of the other methods of diagnosis of bladder tumors (Landman et al, 1998; Ramakumar et al, 1999).

Proteomics

The recently developed method of identification of proteins as markers of tumors has been applied to urinary sediment of patients with tumors of the urinary bladder (Vlahou et al, 2001). The method is experimental and is based on complex technology, using protein chips and mass spectrophotometry. Vlahou identified several **proteins that may be unique to tumors of the bladder**. The results of this study, while not spectacular, were interesting inasmuch as the authors claim 78% sensitivity in the detection of low-grade papillary tumors.

Induced Autofluorescence

Another approach to evaluation of the status of the bladder and therapy is based on direct **instillation of a compound 5-aminolevulinic acid (ALA)**, which is absorbed by mucosal lesions such as flat carcinomas in situ, and induces the accumulation of endogenous **fluorescent protoporphyrins**. The lesions can then be visualized with Krypton ion laser and effectively resected (Kriegsmair et al, 1994). Using this system, a reduction in the recurrence

rate of such lesions was reported (Riede et al, 2001).

Blood Group Antigens

Kovarik et al (1968) suggested that the expression of blood group antigens in bladder tumors may be correlated with prognosis. The fundamental assumption of these studies was that those epithelial tumors that have retained the ability of normal epithelium to express the blood group antigen specific for the blood group of the patient were less likely to recur or progress than tumors that have lost the blood group antigen expression. In the initial studies, erythrocytes of known blood groups were used as markers (Kovarik et al, 1968; Weinstein et al, 1981; Yamase et al, 1981; Limas and Lange, 1982; Flanigan et al, 1983; Cordon-Cardo et al, 1988). Subsequently, serologic methods were developed, and the results were documented by the peroxidase-antiperoxidase system (Coon and Weinstein, 1981). Ultrastructural localization of antisera labeled with colloidal gold has also been documented (De Harven et al, 1987).

The concept, although theoretically valid, has been shown to be of limited practical value. The performance of the test, particularly on small bladder biopsies, was fraught with technical difficulties. The application of the method to cytologic samples has not been fully explored, although several successful attempts have been reported (Borgström et al, 1985; Borgström and Wahren, 1986). At the time of this writing (2004), the method has been abandoned and is reported here for its historical value.

Molecular Genetics in the Diagnosis and Prognosis of Urothelial Tumors

Progress in molecular biology has resulted in a number of observations pertaining to urothelial tumors, some of which may prove to be of clinical value.

P.836

In Situ Hybridization of Chromosomes (FISH)

Using **molecular probes** for identification of individual chromosomes (or their centromeres) by **fluorescent in situ hybridization (FISH)**, Hopman et al (1988, 1989, 1991) could document, in tissue sections, that even the **diploid urothelial tumors have numerical abnormalities of individual chromosomes** (Fig. 23-52D). As summarized by Czerniak and Herz (1995), low-grade papillary tumors show fewer chromosomal abnormalities than high-grade tumors. An increase in the number of **chromosomes 1 and 7 (trisomy) and abnormalities of chromosome 9** were most commonly observed in **low-grade tumors**. Abnormalities in **chromosomes 3, 4, 8, 11, 17, and 18** were most commonly observed in **high-grade tumors**. This information has been applied to **recognition of cancer cells in urinary sediment** by Cajulis et al (1994) using the FISH technique with probes to centromeres of chromosomes 8 and 12. Cajulis documented the presence of **numerical chromosomal abnormalities** in cells in the urinary sediment in a substantial proportion of bladder tumors, some of which were diploid. The FISH technique has found a commercial application with a multicolor probe targeting **synchronously several chromosomes affected in tumors of the bladder and performed on sediment of voided urine** (UroVision, Vysis, Inc., Downers Grove, IL). The probe mixture targets chromosomes 3, 7, 17 and the 9p21 region (Fig. 23-53). The initial study of the probe claimed that the method was **more efficient than cytology in the diagnosis of low- and high-grade tumors and even carcinoma in situ of the bladder** (Sokolova et al, 2000; Halling et al, 2000).

Figure 23-53 Bladder cells from urine hybridized with the UroVysion probe set. A. Composite image from a normal bladder. The UroVysion probe set contains SpectrumAqua CEP 17 (blue-green signals), SpectrumGreen CEP 7 (green signals), SpectrumGold LSI 9p21 (yellow signals), Spectrum Red CEP 3 (red signals). Nuclear DNA is stained with diaminophenylindole (DAPI). Each nucleus contains two signals of each of the four probe colors as expected for diploid chromosomes. **B.** A composite image from a patient diagnosed with transitional cell carcinoma hybridized with UroVysion probe set. Greater than two signals are seen for CEP 17 (aqua), CEP 7 (green), and CEP 3 (red), indicating abnormally high chromosome copy numbers. In addition, both LSI 9p21 signals (yellow) are absent, indicating homozygous deletion of the chromosome 9p21 region (the 9p21 locus includes the tumor suppressor gene p16). (Photographs from Vysis, Inc.)

Other Chromosomal Abnormalities

Further studies of chromosomal abnormalities in bladder tumors were performed by the techniques of **comparative genomic hybridization** (Kallioniemi et al, 1995) or by **molecular cloning with multiple marker probes to individual genes** (Czerniak et al, 2000). These studies documented that frequency of chromosomal abnormalities in bladder tumors is much higher than previously documented by cytogenetic techniques. For example, in chromosomes 4, 8, 9, 11, and 17, Czerniak et al identified **losses in 72 genetic loci, of which 47 were related in a statistical fashion to urothelial neoplasia**. Further, many of these chromosomal abnormalities were **also present in normal and minimally abnormal epithelia adjacent to tumors**. It is postulated that these damaged chromosomal loci represent the location of suppressor genes, most of which are unknown at this time (2004). Most recently, **the microarrays technique** has been used to identify genes that may be characteristic or unique for tumors of the bladder (Brown and Botstein, 1999).

Oncogenes and Tumor Suppressor Genes in Bladder Tumors

Although it is evident from the brief summary above that the issue of genetic abnormalities in bladder cancer has

P.837

not been solved, some of the chromosomal abnormalities correspond to known loci for tumor suppressor genes and oncogenes. As early as 1990, Czerniak et al documented that **ploidy of bladder tumors could be correlated with a mutation of the *ras* oncogene**. The expression of the *ras* gene was **normal in diploid tumors** but was markedly **increased in aneuploid and invasive bladder carcinomas, particularly** when the mutation of the exon in

position 12 was synchronous with an intron mutation. **The mutation could also be demonstrated in cells in voided urine sediment and in normal urothelium several years before the occurrence of invasive cancer** (Czerniak et al, 1992).

Sidransky et al (1991) also observed mutations of the **p53 inhibitory gene** in bladder tumors. It is known that this gene is involved in protecting the normal cell cycle, as discussed in Chapter 3. Several observers reported that the **mutation of the p53 gene is associated with rapid progression and poor prognosis in high-grade tumors of the bladder** (Sarkis et al, 1993; Esrig et al, 1994; Cordon-Cardo et al, 1994). This test is applicable to urinary sediment as reported by Hruban et al (1994) in reference to the bladder cancer of the late Vice President Hubert Humphrey. It is interesting to note, though, that Mr. Humphrey's **diagnosis of carcinoma in situ was established many years earlier by this writer and others by simple microscopic analysis of his urinary sediment and biopsies of bladder** (Koss, 1998, unpublished). Burton et al (2000) quantitated the expression of **p27**, a cyclin dependent inhibitor of cell cycle progression and of **caspase 3**, an important component of the apoptotic sequence, in attempting to establish the prognosis of urothelial carcinoma in situ. In a retrospective study, these authors documented that loss of p27 expression and increased expression of caspase 3 predicted progression of carcinoma in situ to invasive cancer with specificity of 85%.

Another tumor suppressor gene that controls the events of cell cycle is the **retinoblastoma (Rb) gene** (see Chap. 3). Abnormalities of this gene have been observed in **high-grade urothelial tumors with poor prognosis** (Cairns et al, 1991; Ishikawa et al, 1991; Cordon-Cardo et al, 1992).

There is no doubt that, with the passage of time, many additional genes will be identified that participate in carcinogenesis and will perhaps shed light on the genetic sequence of events in urothelial tumors. It remains to be seen, however, whether these labor intensive, costly techniques will soon replace cytology of the urinary tract as means of cancer detection and diagnosis.

The Urologist and Cytology of the Lower Urinary Tract

This brief summary of recent technologic developments in monitoring patients with tumors of the lower urinary tract reflects the **unhappiness of urologists with poor performance of urinary cytology in reference to low-grade, low-stage papillary urothelial tumors, which still require cystoscopic monitoring**. It should be pointed out though that **these tumors are rarely, if ever, threatening the life of the patients** and that they can be easily diagnosed by cystoscopy during follow-up studies. Whether the expense of the new testing methods is ever going to provide lasting benefits to the patients, such as a reduced number of follow-up cystoscopies, is not clear, particularly in view of the high rate of false-positive results, reported by some of the investigators. **The most important benefit of urinary tract cytology is the recognition of high-grade tumors, either as a primary or a secondary event, with specificity unmatched by any of the new systems proposed.**

MALIGNANT TUMORS OF RENAL PARENCHYMA IN URINARY SEDIMENT

The technique of choice in the cytologic investigation of renal parenchymal lesions is the **percutaneous needle biopsy**, discussed at length in Chapter 40. However, **voided urine sediment, and occasionally retrograde brush technology**, may sometimes contribute to the diagnosis of renal parenchymal tumors, if they extend to the renal pelvis and shed

cancer cells in urine. Tumors of renal parenchyma, remote from the renal pelvis, cannot be recognized in the urinary sediment.

Renal Adenocarcinoma

Most adenocarcinomas of the kidney usually originate in the renal cortex. The most common varieties are the **clear cell and granular cell** types. In **histologic material, the** large tumor cells have **large nuclei with prominent nucleoli**, surrounded by abundant, distinctly **granular or clear cytoplasm** that contains both glycogen and lipids. Renal carcinomas have a tendency to invade the renal pelvis and the renal vessels, with resulting **hematuria**, which is not infrequently the first evidence of the existence of the tumor (see Chap. 10).

Cytology

Cytologic detection of renal carcinoma in voided urine cannot occur unless the cancer cells desquamate into the urinary stream. Concomitant hematuria, which occurs often, may render the diagnosis exceedingly difficult. Moreover, the fragile renal cancer cells readily undergo degenerative changes so that even in the absence of hematuria, it is rare to see cells sufficiently well preserved for an unequivocal diagnosis.

Despite these problems, it is sometimes possible to recognize well-preserved cells of renal carcinomas in the urinary sediment. The cancer cells are fairly large, with a delicate, faintly vacuolated or finely granular cytoplasm, that is either eosinophilic or basophilic, and harbors distinctly abnormal, hyperchromatic large

P.838

nuclei with large, often multiple nucleoli (Fig. 23-54). Spindly cancer cells may also occur. In diagnosing renal carcinoma, **one must be certain that the nuclear abnormalities are clearly evident**, since cytoplasmic granularity and vacuolization may be observed in macrophages and in benign cells of urothelial origin, the latter observed in specimens obtained by retrograde catheterization (see Chap. 22). In our experience, the urinary sediment is of questionable value in the diagnosis of primary renal parenchymal cancers, and an unequivocal cytologic diagnosis of renal carcinoma is a rare event.

Figure 23-54 Renal cell carcinoma in voided urine sediment. *A,B.* Show cells with a large, markedly vacuolated cytoplasm, large pale nuclei with prominent nucleoli. *C.* Three small cancer cells with prominent nucleoli, corresponding to the clear cell renal carcinoma shown in *D.*

These personal results are in contradistinction to the experience of other authors who reported a fair measure of success in the diagnosis of renal carcinoma. Umiker (1964) and Meisels (1963) reported between 25% and 50% of renal cancers as diagnosable by cytology. Pisciolli et al (1983) claimed cytologic recognition of renal cancer in 19 of 44 cases. These results could not be duplicated by us.

Hajdu et al (1971) suggested the use of **fat stain (oil red-O) on cells of the unfixed urinary sediment.** The fat stain was positive in the form of distinct intracytoplasmic granules in 14 of 17 patients with renal cancer. The results could not be confirmed by Mount et al (1973) and the method has not received wide acceptance.

Other Types of Renal Carcinomas

Kennedy et al (1990), Mauri et al (1994), and Fallick et al (1997) each reported a case of **the rare carcinoma of the collecting ducts** diagnosed by urine cytology. Contrary to the common form of renal carcinoma, these tumors originate in the tubules of the renal medulla (ducts of Bellini) that open into the renal pelvis (Rumpelt et al, 1991). This may explain the success in the cytologic identification of this tumor.

Larson et al (1998) reported a case of **medullary carcinoma** of the kidney diagnosed in a retrograde brush specimen. The latter tumor is very rare as it occurs in young patients with sickle cell anemia and has a dismal prognosis. So far as one could judge from the illustrations, none of these uncommon tumors had sufficiently characteristic cytologic features for determination of tumor type.

Nephroblastoma (Wilms' Tumor)

This highly malignant tumor of childhood, discussed in Chapter 40, **may shed recognizable cancer cells in the urinary sediment. The cancer cells are small, spherical or elongated, and characteristically form clusters,** an appearance that does not occur with other cells of comparable size, whether inflammatory cells, leukemias, or lymphomas. These cells represent the epithelial component of the complex tumor. **When such cells are found in the urinary sediment of a child, the diagnosis of Wilms' tumor may**

P.839

be entertained (Fig. 23-55). The differential diagnosis includes all other "small blue cell tumors" of childhood and requires clinical data for confirmation.

Figure 23-55 Wilms' tumor in a 9-year-old boy. A-C. The urinary sediment shows clusters of small cancer cells. D. Histology of the tumor.

Malignant Lymphoma

Sano and Koprowska (1965) reported an exceedingly rare case of **primary malignant lymphoma** of the kidney diagnosed on urinary sediment. Cheson et al (1984) reported a case of disseminated lymphoma with renal involvement. The cytologic presentation was comparable to other lymphomas in urinary sediment (see above).

> Table of Contents > II - Diagnostic Cytology of Organs > 24 - The Gastrointestinal Tract

24

The Gastrointestinal Tract

The parts of the gastrointestinal tract that are accessible to cytologic investigation are the **esophagus, stomach, duodenum, colon, and the biliary and pancreatic ducts** (Fig. 24-1).

The methods of sampling are similar for all the organs, except colon.

METHODS OF SAMPLING

The introduction of **flexible fiberglass optics instruments** has not only revolutionized the endoscopy of the entire gastrointestinal tract but also allowed **direct sampling of any visible lesion by cytology or tissue biopsy**. A variety of instruments specially adapted to the inspection of the esophagus,

P.848

stomach, duodenum, and colon are available. Ultrathin endoscopes with a diameter smaller than 6 mm, provided with a video camera, are now available (Van Damm and Brugge, 1999). These procedures can be performed on any patients with radiographic abnormalities or clinical symptoms, or as a part of **cancer prevention programs** in asymptomatic patients at risk for stomach (in Japan) or colon carcinomas. The instruments may also be used for laser treatment of superficial lesions.

Figure 24-1 Schematic representation of portions of the gastrointestinal tract accessible to cytologic investigation. The transverse colon is omitted, to demonstrate the pancreas and the duodenum.

The principles of collection of material for diagnostic sampling are the same for all organs. The instruments are provided with an accessory channel through which a brush, a plastic tube, or a small biopsy forceps may be passed. Thus, **brushing, lavage, or a biopsy** of any area in the gastrointestinal tract may be performed under direct visual control. **Cytologic sampling must be performed prior to biopsy.**

Washings of the esophagus or stomach without endoscopic control are nowadays very rarely used, although this simple technique led to the monumental contributions by Schade (1956, 1959, and 1960A,B) to the diagnosis of early gastric cancer. **An equal volume of 95% alcohol must be added to the fluid immediately after aspiration to preserve the cells.**

Endoscopically directed needle aspiration biopsy for the diagnosis of esophageal and gastric lesions was described by Layfield et al (1992) in a small number of patients with

moderate success. A transbronchial aspiration needle was used in the procedures. There is no evidence that this technique achieved widespread acceptance.

Endoscopic ultrasound-guided needle aspiration biopsy has been proven effective in sampling small lesions of various organs of the gastrointestinal tract (Kosch et al, 1992; Chang et al, 1994; Mallery and Van Damm, 1999; Jhala et al, 2003). Perhaps the most important application of this technique is in sampling of **intramural lesions** and in assessing small lesions of the pancreas (Gress et al, 2001; Afify et al, 2003). For comments on the application of this technique to lesions of the biliary tree, see below.

“Salvage cytology” is a technique proposed by Graham et al (1979) consisting of washing the channel of the endoscopic instrument with saline and collecting the fluid for cytologic analysis into a suction trap. Initially, the technique was intended for use after biopsies (Graham and Spjut, 1979) but Caos et al (1986) reported its successful application without biopsies.

The application of **esophageal and gastro-esophageal balloons and similar techniques** for purposes of cancer detection are described below.

Special methods of cytologic investigation of the colon and rectum and the biliary tract are described further on in this chapter.

P.849

PREPARATION OF SMEARS

Preparation of smears from material obtained by endoscopic instruments is an important part of diagnostic evaluation of patients. Special skills are required for handling of **brushes** and **direct needle aspirates**. Brushing is usually performed to sample a visible lesion. Upon completion of brushing, the brush must be carefully, yet rapidly, withdrawn from the instrument and the **smears prepared without delay**, either by the physician or a trained assistant. Usually a brush yields two to four smears. Alternately, the entire brush may be forwarded to the laboratory for further processing (see Chap. 44). Preparation of smears from aspirates is best performed by a trained cytopathologist or technologist by methods described in Chapter 28.

THE ESOPHAGUS

ANATOMY AND HISTOLOGY

The esophagus is a tubular structure with muscular walls which extends from the pharynx across the diaphragm to the cardia of the stomach. The esophageal lumen is slightly narrowed at the level of thyroid cartilage, the bifurcation of the trachea, and the diaphragm. These are the sites wherein esophageal carcinoma tends to occur (see below). The esophagus is **in close proximity to many vital structures**. In the neck, the larynx and the trachea are immediately anterior; the recurrent nerves run along lateral walls of the esophagus, and the vagus nerves descend along its anterior and posterior walls. In the upper thorax, the esophagus is in contact with the trachea and the arch of the aorta. At the level of the heart, the left auricle is in close proximity. Thus, **cancers of esophagus not only may obstruct its lumen, but also may invade and damage several vital organs**.

The esophagus is **lined by nonhornifying squamous epithelium** (Fig. 24-2A). **Islands of gastric epithelium may be found in the areas immediately adjacent to the cardia and, rarely, elsewhere within the esophagus**. Small, **mucus-producing glands** are found in the submucosa. The epithelium rests on a connective tissue layer, the submucosa or the **lamina**

propria, which separates the epithelium from the **muscle layers** or the **muscularis propria**.

NORMAL CYTOLOGY

The cytology of the esophageal aspirates, brushings, and washings in the absence of disease is **extremely simple**. The smears are composed essentially of **superficial squamous cells with vesicular nuclei, identical to those observed in sputum samples** (Fig. 24-2B). Less frequent are **smaller squamous cells derived from the deeper layers of the epithelium and provided with nuclei of similar sizes and configuration to the superficial cells**. **Occasionally, benign squamous “pearls,” may be noted**. It is not unusual to find **swallowed cells of respiratory origin, such as dust-containing macrophages and ciliated bronchial cells** (see Chap. 19). Also, **gastric epithelial cells**, singly or in clusters, may occur (see Fig. 24-16). **Foreign material**, especially plant (vegetable) cells, may be present if there is an obstruction of the esophageal lumen. For description of these contaminants, see Chapter 19.

BENIGN DISORDERS

Acute and Chronic Erosive Esophagitis

This group of diseases of varying etiology is very important in diagnostic cytology, because it produces **cells that may be confused with cancer**. Esophagitis may have different causes such as **trauma, acid reflux from the stomach, a reaction to swallowed corrosive liquids, cardiospasm** of long standing, **Plummer-Vinson syndrome** (also known as **sideropenic dysphagia**, a syndrome of atrophy of the esophageal epithelium and iron deficiency anemia), some forms of **avitaminosis, scleroderma** (or **systemic sclerosis of connective tissue**, affecting primarily the skin), and **hiatus hernia**. It is of interest that, in older women, **systemic sclerosis** may be associated with the presence of persisting **fetal DNA**, suggesting that this disease may be an immune response to remote past pregnancies (Artlett et al, 1998). It is not known whether **chronic erosive esophagitis**, a rare, sometimes fatal disease, is related to any of these disorders. A **drug, alendronate**, an inhibitor of bone resorption (osteoporosis) has been shown to cause a **chemical esophagitis** in some patients with erosions and ulcerations of esophageal mucosa and thickening of the esophageal wall. In some cases, the disease is severe and disabling (De Groen et al, 1996).

Histology

The histologic lesion in esophagitis is **mucosal erosions or ulcerations** varying in number, depth, and configuration. There is moderate infiltration of the stroma with inflammatory cells. The surface of the lesion may be covered with granulation tissue or fibrin. **Chronic erosive esophagitis** is characterized by **loss of superficial epithelial layers (mucosal erosions)** (Fig. 24-2C). Squamous metaplasia of the submucosal glands may occur in this disorder.

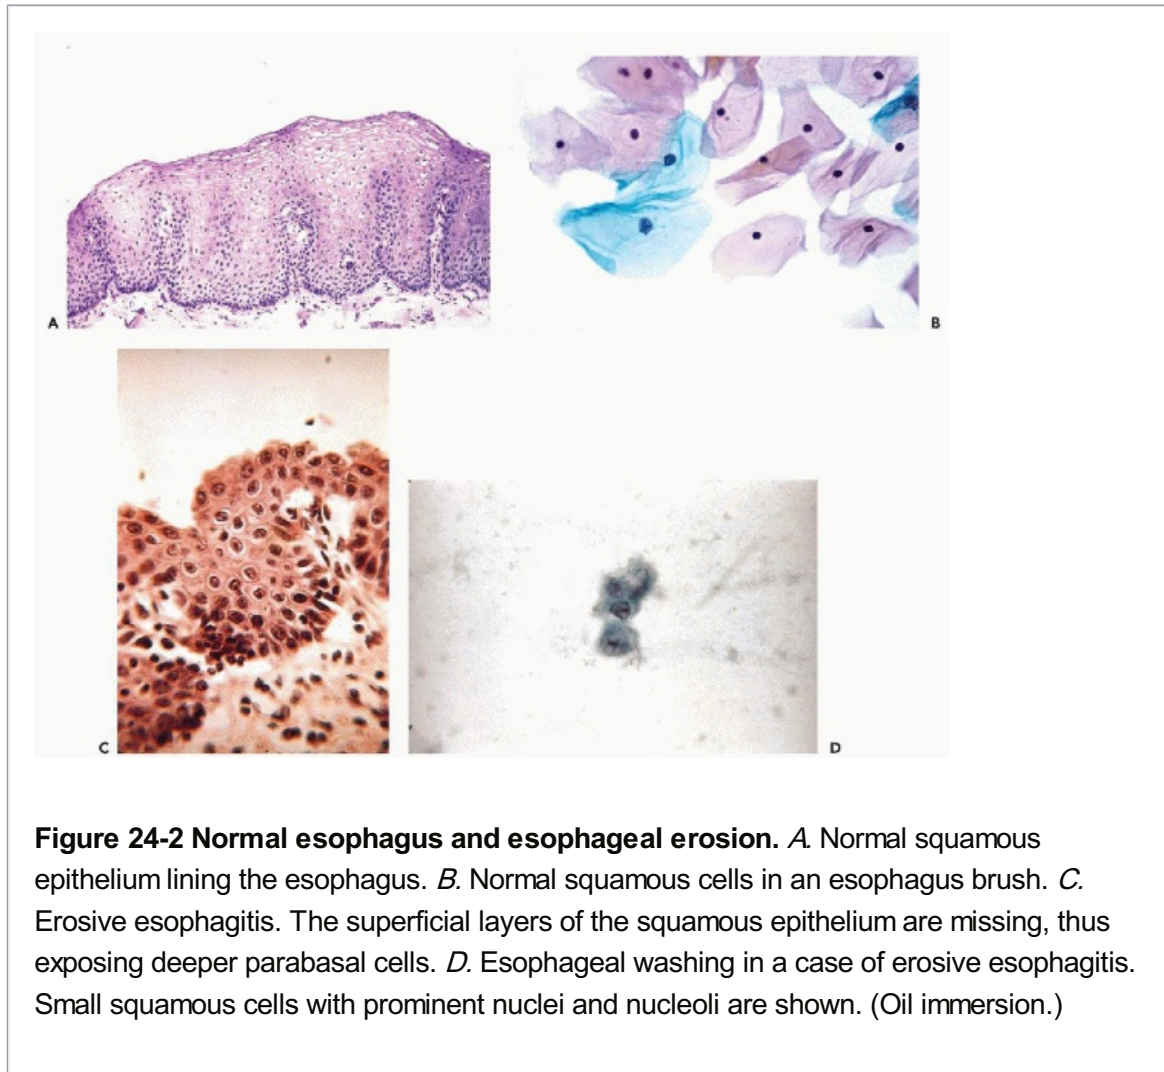

Cytology

Cells desquamating from the eroded esophageal epithelium are derived from the deep layers and are of the same size as **parabasal squamous cells, occurring singly and in small clusters**. The cytoplasm is evenly distributed and the cells do not vary much in size. In clusters, there is good adherence of the cells to each other. The most outstanding features of the **relatively large, somewhat hyperchromatic nuclei of these cells, sometimes show isolated clumps of chromatin and, occasionally, large nucleoli that may lead to an**

erroneous diagnosis of cancer (Fig. 24-2D). Careful attention to cellular detail helps in the correct interpretation of the cytologic findings. The cells seen in erosive esophagitis

P.850

may be similar to those observed in “**repair**” of squamous epithelium or in **pemphigus** (see Fig. 21-10).

A recently recognized entity, **eosinophilic esophagitis**, has been observed mainly in children but also in adults (Liacouras, 2003; Dahms, 2004). Clinically, the disease causes painful reflux esophagitis that **mimics gastroesophageal reflux disease (GERD)** but does not respond to antacid treatment. Dense eosinophilic infiltrate of the esophageal wall has been observed in biopsies (Straumann et al, 2004). There are no reported cases of this entity diagnosed on cytologic sampling.

Herpetic Esophagitis

Clinical Findings and Histology

Many years ago, Berg (1955) emphasized the occurrence of this disease in cancer patients who, in the course of treatment, sustained a **surgical or radiation injury** to the esophagus. **Immunosuppressive therapy, cytotoxic anticancer drugs, and acquired immunodeficiency syndrome (AIDS)** have contributed to an increased frequency of this disease (Lightdale et al, 1977). Most patients have vague complaints referable to the

esophagus, such as retrosternal pain or mild dysphagia. Herpetic esophagitis produces **extensive, although superficial, ulcerations** of the esophageal mucosa. In biopsies, **intranuclear eosinophilic inclusions** are observed within the epithelial cells. The use of cytology resulted in primary diagnosis in several cases. Surprisingly, **in some patients, there was no past history of immune deficiency or immunosuppression**. It is, therefore, possible that the disease is more common than hitherto anticipated. We have observed apparent **simultaneous involvement of the esophagus and the bronchial tree**.

Cytology

The disease may be diagnosed in material obtained from the esophagus by washings, or brushing. The cytologic findings

P.851

are identical with those observed in the material from the female genital tract (see Fig. 10-29), and the respiratory tract (see Chap. 19 and Fig. 19-36). **Multinucleated cells with molded "ground-glass," opaque nuclei and cells with intranuclear eosinophilic inclusions are observed** (Fig. 24-3A,B).

Figure 24-3 Infectious disorders of the esophagus. *A*. Typical cell changes of herpesvirus infection showing large multinucleated squamous cells with eosinophilic intranuclear inclusions. *B*. Another example of cells in herpetic esophagitis with large eosinophilic intranuclear inclusions. *C*. Pseudohyphae and yeast form of *Candida albicans* (moniliasis) in a patient with AIDS. *D*. *Nocardia* in esophagus. The GMS silver stain shows complex filaments of this bacterium. (*B*: Oil immersion.)

Esophageal Infections in AIDS

Esophagitis is a common early manifestation of AIDS. ***Candidiasis* (moniliasis)** (Fig. 24-3C), **herpetic esophagitis** (see above), **cytomegalovirus infection** (see Fig. 24-17B), and other infectious agents such as ***Nocardia*** may be identified in cytologic samples obtained during esophagoscopy (Fig. 24-3D). Geisinger (1995) stressed that **cytologic techniques are much**

superior to biopsies in the diagnosis of Candida esophagitis. Teot et al (1993) reported a case with **simultaneous herpetic and cytomegalovirus esophagitis in AIDS.** Borczuk et al (1998) described a case of esophagitis caused by *Trichomonas*, diagnosed in esophageal brushings, in a male patient with AIDS.

Tuberculous esophagitis has been described in India where this disease is prevalent (Jain et al, 1999). The finding of clusters of **elongated epithelioid cells** and occasional **Langhans' type giant cells**, in a background of inflammatory exudate, is suggestive of this rare event. Because of a marked increase of tuberculosis in AIDS patients, it may be anticipated that such cases will soon occur in the Western world as well.

Esophageal Diverticula

Esophageal diverticulum is an **outpouching of the esophageal epithelium** through the muscular wall of the organ. A diverticulum distended by accumulated food particles may produce **symptoms of esophageal obstruction** similar to those of cancer. There are no cytologic abnormalities known to occur in the presence of a diverticulum. However, rare **cancers originating within the diverticula** may be diagnosed by cytology (see below).

BARRETT'S ESOPHAGUS (COLUMNARLINED ESOPHAGEAL EPITHELIUM)

Clinical and Histologic Data

The syndrome, first described by Barrett in 1950, consists of a **replacement of the distal esophageal squamous epithelium by columnar epithelium of gastric or intestinal**

P.852

type, associated mainly with chronic gastroesophageal reflux disease (**GERD**), and sometimes with hiatus hernia and esophageal stricture (Mossberg, 1966; Burgess et al, 1971; Spechler and Goyal, 1986; Chandrasoma et al, 2001; Shaheen and Ransohoff, 2002). The segment of the replaced esophageal mucosa may be **short or long** (recent summaries in Glickman et al, 2001 and Spechler, 2002). The symptoms associated with Barrett's syndrome are **dysphagia, regurgitation, heartburn, and pain**. Episodes of **acute obstruction** may occur, sometimes caused by **peptic ulcers, similar to gastric ulcers** (Fig. 24-4). In such cases, the radiologic examination may reveal a stricture that may mimic to perfection the appearance of an esophageal carcinoma (see Fig. 24-4A), although there is usually a preservation of esophageal peristalsis above and below. After treatment, the stricture may regress significantly (Fig. 24-4D). **Barrett's syndrome is, per se, a benign disorder, but has now been recognized as a risk factor for adenocarcinoma of the esophagus and, to a lesser extent, of gastric cardia** (Lagergren et al, 1999). **Cytologic techniques may be used to monitor patients with Barrett's esophagus to identify malignant transformation and precancerous states, as described below.**

Figure 24-4 Barrett's esophagus with ulcer formation. *A.* Narrowing and obstruction of the esophagus in a barium swallow in a 56 year old man. *B.* Brushing of the obstructed area revealed benign columnar cells of intestinal type and normal squamous cells. *C.* Biopsy of the affected area shows a transition between normal squamous epithelium on left and gastric type epithelium on right, characteristic of Barrett's esophagus. *D.* Barium swallow after conservative treatment. The narrowing and the esophageal occlusion seen in *A* have nearly disappeared and the patient became asymptomatic.

Histologic findings show an abrupt transition from the normal squamous epithelium to **mucus-producing columnar epithelium of gastric type or of intestinal type with goblet cells** (see Fig. 24-4C). The epithelium may form **cysts** wherein Rubio et al (1989, 1992) observed occasional presence of **ciliated columnar cells**, although this finding was much more common in papillary carcinomas (see below).

Cytology

Although the diagnosis of uncomplicated Barrett's esophagus is usually established by esophagoscopy and biopsies, **cytologic examination of esophageal brush specimens, aspirates or washings**, may be valuable in establishing baseline data for comparison with future abnormalities occurring during the follow-up of these patients. The **smears, containing mucus-producing benign columnar cells and goblet cells, usually in clusters, characteristic of mucus-producing intestinal epithelium**, are diagnostic of Barrett's esophagus (see Fig. 24-4B). The glandular cells have **small, spherical, nuclei of even sizes**. The peripheral nuclei of the goblet cells may appear a bit darker. We have not

P.853

observed the **ciliated columnar cells** described by Rubio (1989), except for **swallowed cells of bronchial origin**. Fennerty et al (1995) attempted to diagnose this disorder by esophageal balloon technique (described below) without success. Malignant changes in Barrett's esophagus are described below.

BENIGN TUMORS

Focal Hyperplasia and Papillomas (Condylomas) of Squamous Epithelium

In 1982, Syrjänen et al described a rare **papilloma-like lesion of the squamous epithelium** of the esophagus, akin to a **condyloma acuminatum**, and postulated that human papillomavirus (HPV) may be a factor in the genesis of this tumor. Winkler et al (1985) confirmed this hypothesis by documenting the presence of HPV antigen in two such lesions and in 11 of 73 “**focal hyperplasias,**” **some of which resembled “flat condylomas” with significant koilocytosis and nuclear abnormalities.** Further evidence that HPV is present in papillomas was provided in case reports (Yamada et al, 1995; Politoske, 1992) and by Lavergne and de Villiers (1999) who confirmed the presence of the virus in 4 of 11 papillomas of the esophagus by molecular analysis. Apparently, none of these lesions progressed to cancer. It is of note, though, that Syrjänen (1982) observed “flat condylomas” at the periphery of invasive esophageal cancers. There is no known cytologic presentation of these lesions but it is likely that koilocytes should be observed in smears.

Granular Cell Tumor or Myoblastoma

A case of **granular cell myoblastoma** of esophagus diagnosed on esophageal brushings was described by Cordoba et al (1998). The lesion is very unusual in this location. The cytologic presentation of this tumor has been described in reference to the lung (see Chap. 20) and the breast (see Chap. 29).

Leiomyoma

We had the opportunity to study esophageal lavage and brush specimens from several cases of leiomyomas of the wall of the esophagus. The tumors could not be recognized in cytologic samples.

SQUAMOUS CARCINOMA AND ITS PRECURSORS

Epidemiology and Clinical Aspects

Squamous carcinoma is, by far, the most common type of esophageal cancer. The disease may affect any part of the esophagus, but occurs preferentially in **segments of slight narrowing:** at the level of the thyroid cartilage, bifurcation of the trachea, and the diaphragm. As a general rule, fully developed esophageal cancers cause **obstruction of the esophagus, resulting in difficulties of swallowing and dysphagia.**

Squamous cancer of the esophagus is a quasi-endemic disorder in northeastern Iran, in parts of China, among the Chinese in Singapore, among Africans in southern Africa, and among men in Brittany (France) (Enzinger and Mayer, 2003). In the United States, the disease is relatively uncommon; African American men appear to be more prone to it than other ethnic groups. In general, the disease is more common in males than in females. Epidemiologic data suggest that intake of hot beverages, cigarette smoking, and alcohol consumption are possible risk factors (Tavani et al, 1994; Enzinger and Mayer, 2003). Recent studies in China failed to reveal any consistent risk factors except, perhaps, diet (Li et al, 1989; Yu et al, 1993). Auerback et al (1965) demonstrated a high frequency of squamous carcinoma in situ of the esophagus among smokers.

The **prognosis of esophageal squamous carcinoma** is stage related. The overall survival is about 20% (Lerut et al, 1992; Goldminc et al, 1993). Izbicki et al (1997) pointed out that the

prognosis of patients with clinical stage I disease, confined to the wall of the esophagus, may be modified by finding **occult micrometastasis** in regional lymph nodes stained with an epithelial antibody. Stockeld et al (2002) described the use of **fine needle aspiration (FNA) biopsy technique** for prognosis of esophageal squamous cancer. Aspirates of the esophageal wall, obtained at 2 cm intervals, led to the discovery of microscopic tumor spread in onethird of the 52 investigated patients. The results were more accurate than synchronous esophageal brushing or multiple biopsies. The ratio of benign to malignant cells in the aspirated samples appeared to be of prognostic significance.

Kwong et al (2004) studied chromosomal aberrations in esophageal squamous cancer by comparative genomic hybridization. Numerous gains and losses were observed but **gain in the short arm of chromosome 12 (+ 12p)** predicted poor prognosis after surgery, at least among the Chinese.

Adenocarcinoma occurring in Barrett's esophagus is discussed below.

Human Papillomavirus in Squamous Cancer of the Esophagus

Invariably, as with all squamous cancers, the question of **human papillomavirus (HPV) as a factor in the genesis of this tumor** was raised (Syrjänen, 1987). HPV DNA presence in five invasive esophageal cancers was first reported by Kulski et al (1986). Subsequently, Chang et al (1992) reported the presence of HPV in 25 of 51 (49%) **biopsies** from Chinese patients with invasive esophageal carcinoma. In 16 of these 25 specimens, HPV types 16 and 18 were documented by in situ hybridization. Other types of HPV were observed in the remaining 7 patients. In the same study, 53 of 80 **cytologic preparations**, also from asymptomatic Chinese patients from a high-risk area, were positive for HPV by filter in situ hybridization. HPV was also detected in cells of 2 of 9 patients without cytologic abnormalities, in 3 of 6 patients with "mild dysplasia," in 25 of 31

P.854

patients with "moderate dysplasia," in 19 of 28 patients with "severe dysplasia," and in 4 of 6 patients with invasive carcinoma. In an update of this study, Chang et al (2000) reported that 16.9% of 700 Chinese patients with esophageal carcinoma were HPV positive, with 27% of the positive samples containing the "high risk" HPV types 16 and 18.

These data were either confirmed or contested in several papers. Thus, Cooper (1994) and He (1997) observed HPV in about 15% of esophageal cancers. De Villiers et al (1999), known for impeccable laboratory technique, confirmed the presence of HPV of various types in 17% of samples from Chinese patients. Takahashi et al (1998) and Kawaguchi et al (2000) **observed that the presence of HPV was associated with mutations of the p53 gene.**

On the other hand, Smits et al (1995) from the Netherlands, Benamouzig et al (1995) from France, and Mizobuchi et al (1997) from Japan, were unable to identify HPV in their many samples. In a study of 51 patients with squamous carcinoma from three North American cities, only **one** patient's tumor contained HPV type 16 (Turner et al, 1997).

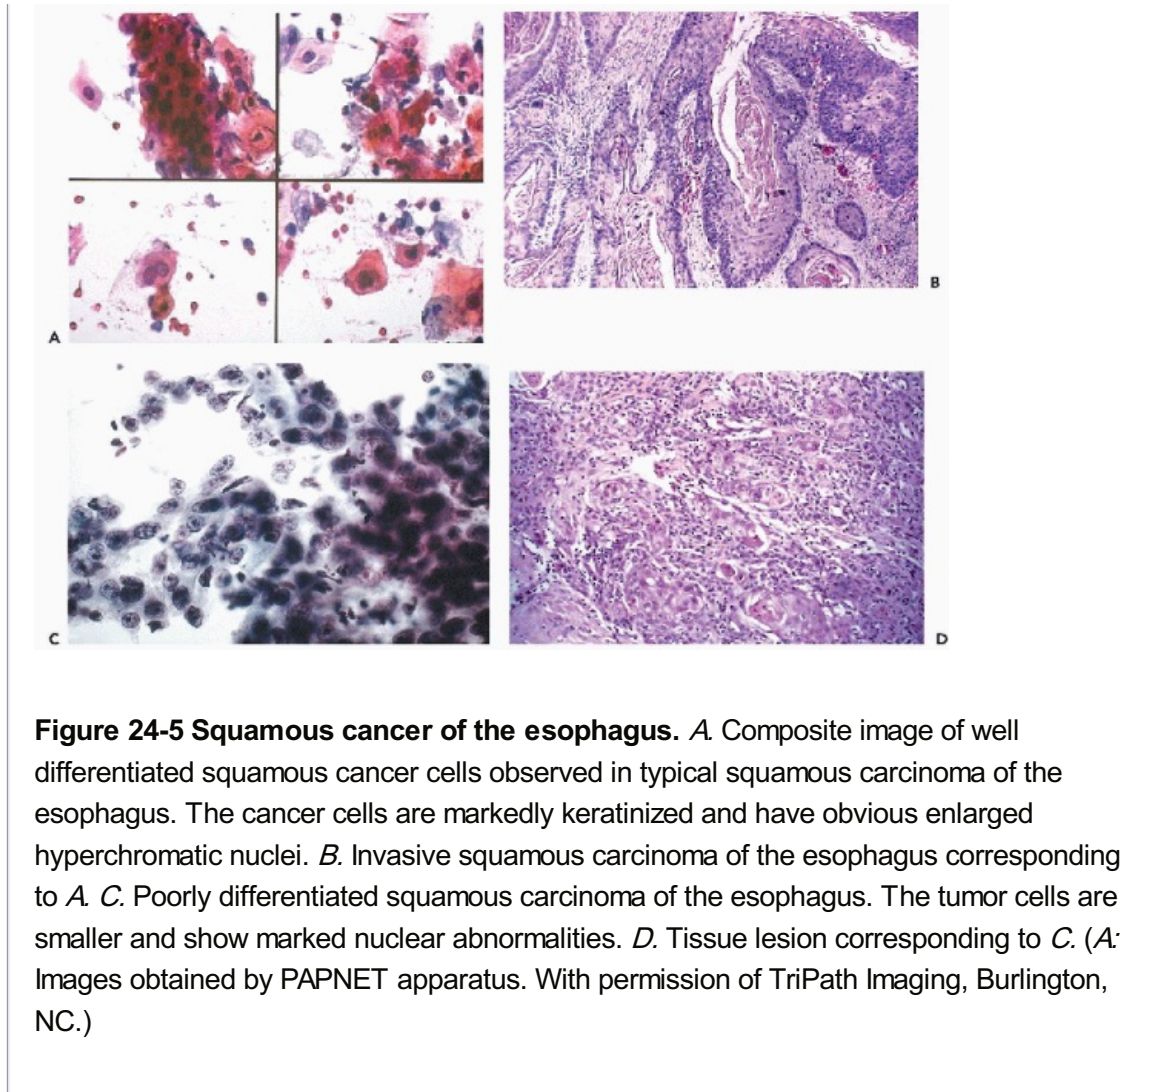

Figure 24-5 Squamous cancer of the esophagus. *A.* Composite image of well differentiated squamous cancer cells observed in typical squamous carcinoma of the esophagus. The cancer cells are markedly keratinized and have obvious enlarged hyperchromatic nuclei. *B.* Invasive squamous carcinoma of the esophagus corresponding to *A.* *C.* Poorly differentiated squamous carcinoma of the esophagus. The tumor cells are smaller and show marked nuclear abnormalities. *D.* Tissue lesion corresponding to *C.* (*A:* Images obtained by PAPNET apparatus. With permission of TriPath Imaging, Burlington, NC.)

It is quite evident that the issue of the role of HPV in esophageal carcinoma has not been definitely settled but there appears to be little doubt that in tumors from some patients, mainly Chinese and Japanese, the virus is present (Galloway and Daling, 1996). **Since a person-to-person transmission of HPV is unlikely in these patients, an activation of the latent viral infection is a more likely explanation of these findings.**

It is of note that Wang et al (1999) detected **Epstein-Barr virus (EBV)** in squamous cancer in Taiwan.

Histology

Histologic appearance of squamous cancer may vary in the degree of differentiation from **well differentiated, highly keratinized (verrucous) types** (Fig. 24-5B) to **poorly differentiated squamous cancer** (Fig. 24-5D) and, rarely, **small-cell** (oat cell) type of carcinoma (Rosen et al, 1975; Bogomoletz et al, 1989). **A basaloid variant**, resembling a basal cell carcinoma but with a highly malignant behavior, was described (see Fig. 24-6D) (Abe et al, 1996). **Focal**

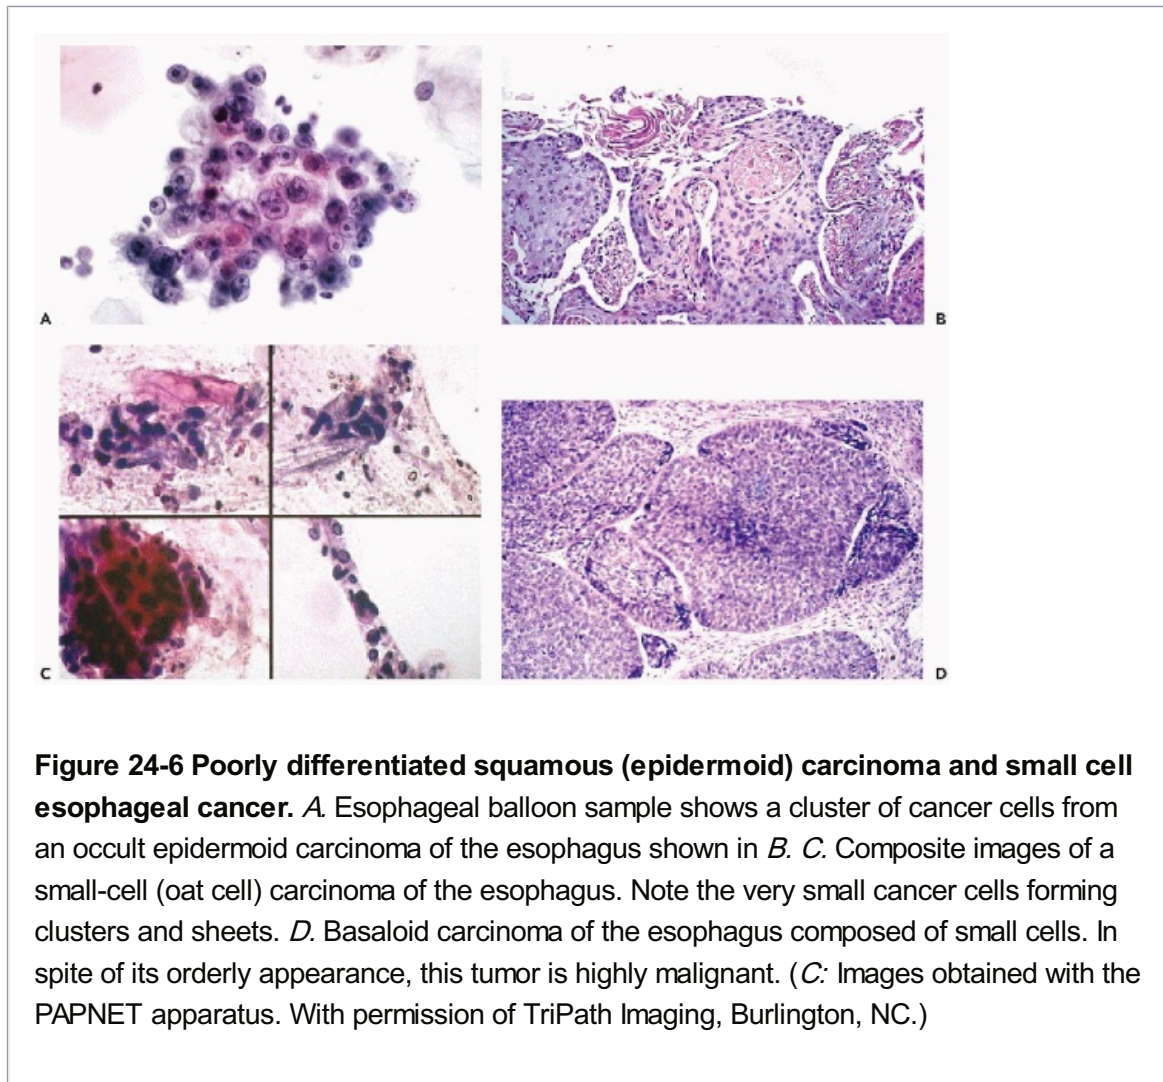

P.855

glandular features may be observed in a substantial proportion of epidermoid carcinomas (Kuwano et al, 1988). Some of the poorly differentiated carcinomas may show **endocrine granules** in electron microscopy (Reyes et al, 1980).

Cytology

As discussed above, these tumors may occur in a variety of grades and degrees of differentiation. The cytologic findings in esophageal washings or brushings closely reflect these structural variants and are similar to those described for bronchogenic carcinomas of similar histologic types (see Chap. 20).

The well-differentiated squamous carcinoma produces **heavily keratinized abnormal squamous cells, singly or in clusters, with either completely pyknotic, hyperchromatic nuclei, or with nuclear shadows**, much in the manner described for similar cancers of the bronchus (Fig. 24-5A; see Chap. 20). **Koilocyte-like cells** with large, hyperchromatic nuclei and perinuclear clear zones or halos are sometimes observed in such tumors. There is no good correlation between these cells and the presence of HPV.

Less well-differentiated squamous cancers of large cell type (epidermoid carcinomas) are characterized by smaller cancer cells with very **scanty basophilic cytoplasm, often forming clusters**, particularly in brush specimens (Figs. 24-5C and 24-6A). The **nuclear abnormalities in the form of enlargement, hyperchromasia and large nucleoli** are usually quite evident. The diagnosis of tumor type depends largely on the finding of squamous cancer cells with eosinophilic cytoplasm, which may be very scarce.

Small cell carcinomas, the most **anaplastic varieties of squamous cancer**, produce **cancer cells that often are very small, with abnormally large, hyperchromatic nuclei and very scanty cytoplasm** (Fig. 24-6C). The corresponding tissue sections may sometimes

show the “basaloid” tumor pattern (Fig. 24-6D). Horai et al (1978), Reid et al (1980), and Imai et al (1978) described several examples of such carcinomas. Hoda and Hajdu (1992) pointed out that, **contrary to oat cell carcinoma of the bronchus, cell molding**

P.856

was uncommon in the esophageal tumors and that the evidence of **endocrine activity** in these tumors **was insecure**.

Squamous or epidermoid carcinomas of the distal end of the esophagus may extend into the gastric cardia and **fail to produce radiographic abnormalities of cancer on cursory examination**. Cytologic examination, either by esophageal or gastric brushings, may be of critical diagnostic importance (Fig. 24-7).

The use of fine needle aspiration of the esophageal wall, for diagnosis and prognosis of squamous cancer, proposed by Stockeld et al (2002) was described above.

Precursor Lesions of Squamous Carcinoma and Their Detection: Lessons From China

In the 1961 and 1968 editions of this book, it was anticipated that **carcinoma of the esophagus must be preceded by precancerous epithelial changes, such as carcinoma in situ and related abnormalities**. In the Western world, the knowledge of precancerous squamous lesions of the esophagus is scarce. There are several cases on record in which **squamous carcinoma in situ** and related lesions had been observed as incidental findings (previous editions of this book; Imbriglia and Lopusniak, 1949; Auerback et al, 1965; Ushigome et al, 1967; Koss et al, 1998) or as a lesion accompanying invasive carcinoma (Suckow et al, 1962; Kuwano et al, 1988). However, the hypothesis could be confirmed only by the extensive cytologic and histologic studies of esophageal cancer conducted by Chinese investigators.

Figure 24-7 Poorly differentiated squamous carcinoma involving distal esophagus and adjacent gastric cardia. The tumor was roentgenologically occult. *A,B.* Clusters of small malignant squamous cells in esophageal lavage. *C.* Squamous carcinoma in situ involving lower esophagus with transition to invasive carcinoma, shown in *D*.

The stimulus for the Chinese studies was the **very high prevalence rate of esophageal cancer in certain areas of central and northern China** (Yang, 1980; Shu 1984, 1985). It is of incidental interest that, in the same areas of China, **chickens are susceptible to cancer-like tumors of the gullet**. The relationship of these tumors to human cancer is not understood. Except for its possible association with diet and human papillomavirus, the causes of human esophageal cancer in China and its relationship to the tumors in poultry, remain unknown at the time of this writing (2004).

The Chinese investigators proposed that **prevention of esophageal cancer could be based on the same principles as detection of precursor stages of cancer of the uterine cervix**. If cytologic samples, obtained in asymptomatic, high-risk populations, could lead to the discovery of precancerous lesions, then **early surgical intervention** or **photodynamic therapy** could prevent invasive esophageal cancer with its very high mortality rate (Yang et al, 2002). The **instruments** used in the cytologic investigations were small,

P.857

inflatable **plastic balloons with abrasive surface** (Fig. 24-8), modifications of a gastric balloon that was described in 1950 by Panico et al. The balloon was attached to a narrow-caliber tube with color markers to indicate the position of the balloon in the esophagus. The balloon could be easily swallowed in deflated state, moved by peristalsis to the cardia, inflated, and slowly withdrawn to the level of the cricoid cartilage. At this point, the balloon is deflated and withdrawn. The abrasive surfaces of the balloon contained cells scraped from the surface epithelium that could be examined in smears. The method, which was tested in our institution, caused trivial discomfort to the patients and was well accepted (Greenebaum, 1984).

Figure 24-8 Esophageal balloon, collapsed (*bottom*) and distended with air (*top*). Note the rugosity of the surface that serves to obtain cell samples from the esophagus. The balloon is connected to a plastic tube with markers to indicate the position of the balloon in the esophagus. (Courtesy of Dr. Yi-Jing Shu, St. Gallen, Switzerland.)

The **accuracy of balloon sampling** was tested in China on 1,861 patients with overt

esophageal cancer, documented by biopsy. The accuracy varied from 87.2% to 99.0%, averaging 94.9% (summary in Shu 1984, 1985). As reported by Shu in 1984, the **cytologic sampling by balloon proved to be much superior to either endoscopy or radiologic examination for the diagnosis of precursor lesions and early invasive squamous carcinoma**. In an elaborate statistical analysis, Dawsey et al (1994A,B) compared the **results of cytologic sampling with the incidence rates of esophageal squamous carcinoma** in the Linxian province of China and concluded that the **esophageal balloon cytology successfully identified persons at increased risk for esophageal cancer**. This was confirmed for the Anyang County of China by Yang et al (2002). It is not known how the balloon method would compare with contemporary endoscopy, which because of cost and limited availability could not be used on a very large scale for purposes of esophageal cancer detection.

Several **other methods** to study esophageal cytology were developed. Jaskiewicz et al (1987) used a **small sponge, attached to a string and packaged in an easy-to-swallow gelatin capsule** to study patients in South Africa. A similar system was described by Sepehr et al (2000) as better acceptable to patients. Qin and Zhou (1992) described an **elastic plastic tube** for esophageal sampling and reported an accuracy of 96% in the diagnosis of cancer.

Results of Screening

The first results of the population survey were presented in the Fourth International Cancer Congress in Florence, Italy in 1974 by an anonymous group representing the Chinese Academy of Medical Sciences. A cytologic survey of 17,471 persons over 30 years of age was conducted in the Henan Province in northern China. **“Dysplasia”** of the esophageal epithelium was observed in 276 patients, mostly below the age of 40, whereas invasive carcinoma in this population usually occurred in patients older than 40. **Follow-up study of the patients with “dysplasia,”** some over a period of 7 to 10 years, disclosed that 30.3% of them developed esophageal carcinoma, in 27.3% the original lesion persisted unchanged, and in 42.4% the changes either regressed to mild dysplasia or reverted to normal. In histologic studies of 67 patients, **the progression of dysplasia of various types to carcinoma in situ could be observed in many specimens**. It was the conclusion of this study that **“marked dysplasia” must be considered a precancerous lesion**. During the intervening years and changing political conditions in China, the names of the investigators became known (summary in Shu 1984, 1985), and the results of several surveys became available.

As related by Shu in 1984, there is no doubt that mass screening for esophageal carcinoma in high-risk areas of China had a major beneficial effect. Before screening was instituted, the diagnosis of carcinoma in situ or early invasive carcinoma was 2 per 1,000 in low-risk areas and 10 per 1,000 in high-risk areas. Screening of 81,187 asymptomatic people over the age of 30 in the high-risk Henan Province resulted in the discovery of 880 esophageal cancers (*a huge prevalence rate of 1%!*), of which 649 (73.7%) were early and treatable by surgery (Shu, 1984). Less is known about survival of these patients, but Dr. Shu assured me that most of the treated patients survived 5 years or longer with a good quality of life. This information must be compared with a survival of about 10% to 25% of patients with invasive squamous cancer of the esophagus commonly observed in the Western world (Ide et al, 1994; Lieberman et al, 1995). Kwong et al (2004) reported that, among Chinese patients with esophagus cancer, those showing a **gain of the short arm of chromosome 12 (+p12)** in the tumor had poor outcome after surgical treatment, regardless of stage of disease.

Screening for Esophageal Squamous Cancer in Countries Other Than China

The accomplishments of the Chinese scholars found several imitators. Thus, Berry et al (1981) attempted a similar project in South Africa (where the rate of esophageal cancer is very high among some black populations), resulting in the discovery of 15 occult invasive carcinomas and carcinomas in situ in 500 patients studied. Dysplasia was illustrated, but the clinical significance of the lesion was not discussed. Similar results were reported by Jaskiewicz et al (1987) from a high-risk rural population in Transkei (South Africa); in

P.858

five patients, dysplastic changes progressed to invasive cancer.

To our knowledge, the Chinese experience has not been duplicated in the Western countries, except for the work in this laboratory. Greenebaum et al (1984) studied 96 high-risk Montefiore Hospital patients in New York City by the balloon technique. The selected patients had prior cancers of the larynx or pharynx, or were alcoholics and heavy cigarette smokers. Greenebaum unexpectedly found **three occult recurrent oropharyngeal cancers and one carcinoma in situ of the esophagus, observed in a man with prior history of squamous carcinoma of the larynx.** The biopsy of the esophagus disclosed fragments of squamous cancer in the absence of radiologic abnormalities.

Classification of Precancerous Lesions in China

Based on cytologic and histologic criteria, the Chinese investigators divided the precancerous lesions into two groups: **dysplasia and carcinoma in situ. The criteria were derived from the classification of precancerous lesions of the uterine cervix** (see Chap. 11). **Lesions with more orderly epithelial growth, surface differentiation, and relatively minor nuclear abnormalities were classified as *dysplasia* and lesions with more significant atypia were classed as *carcinoma in situ*.**

The **dysplasias were further subdivided into mild, moderate, and severe, based mainly on cytologic criteria** (see below). The true significance of dysplasia is not clear. Although, in some patients, the lesions either failed to progress or regress, there is no doubt that, **in a substantial number of untreated patients, invasive cancer of the esophagus was subsequently observed** (Shu 1984, 1985). The same conclusion was reached by Sugimachi et al (1995), who considered "dysplasia" as an early carcinoma of the esophagus. In any event, **the insecure behavior of the precancerous lesions of the esophagus is remarkably similar to lesions of the uterine cervix** (see Chap. 11).

Cytology

Much of the current knowledge of cytology of precursor lesions comes from Chinese sources (summaries in Shu, 1984, 1985; Shen, 1984). There is a remarkable similarity between the cytologic presentation of carcinoma in situ and related lesions of the esophagus and those of the uterine cervix (see Chap. 11). **As in the uterine cervix, the lesions may be conveniently divided into high grade and low grade.**

High-Grade Lesions

The squamous cancer cells derived from high grade lesions (**high grade dysplasia, carcinoma in situ**) are of the parabasal variety. **The nuclear abnormalities consist of enlargement and hyperchromasia; the cytoplasm is scanty, resulting in a high nucleocytoplasmic ratio** (Fig. 24-9). Cell clustering is common. Shu (1984, 1985) **illustrated**

several examples of progression of dysplasias to carcinoma in situ and, in some cases, to invasive carcinomas over a period of 2 to 4 years.

There are very few cases of **carcinoma in situ diagnosed by cytology** in the Western world. Besides the case reported by Imbriglia and Lopusniak (1949), one case of a lesion approaching carcinoma in situ was personally observed in esophageal washings in a 59-year-old man with an esophageal diverticulum and symptoms of obstruction, leading to the clinical diagnosis of esophageal cancer. The lesion was characterized by **typical dyskaryotic (dysplastic) superficial and parabasal squamous cells**. The biopsies, which, unfortunately, were obtained after an initial short course of radiotherapy, localized the lesion to the diverticulum, which was subsequently successfully resected. The histologic appearance of the epithelium disclosed nuclear abnormalities and some degree of disarrangement of the component cells. One **carcinoma in situ** was recognized during balloon screening of a high risk population by Greenebaum et al (1984), and another during analysis of esophageal cytologic abnormalities by a neural net-based scanning system (Koss et al, 1998). In both cases, the **smears contained squamous cancer cells, singly and in clusters, that could not be differentiated from an invasive squamous cancer** (Fig. 24-10). The last patient who had a history of esophageal stricture and necrotizing esophagitis, was alive without evidence of esophageal cancer 3 years after the diagnosis. These anecdotal cases confirm the insecure prognosis of precursor lesions of esophageal squamous carcinoma.

Low-Grade Lesions

Low-grade lesions of the esophagus (mild or moderate dysplasia; Fig. 24-11) are characterized by **well-differentiated superficial and intermediate squamous cells with marked nuclear enlargement and hyperchromasia**. In some patients, **koilocytes** may be observed. The resemblance of these cell abnormalities to dyskaryosis (dysplasia) of cervical squamous cells is remarkable (see Chap. 11).

ADENOCARCINOMA AND ITS PRECURSORS

Clinical Data and Natural History

Although only about 3% of esophageal cancers are adenocarcinomas, this disease has generated an enormous amount of attention because of its **association with "columnarlined epithelium" or Barrett's esophagus** (Haggitt et al, 1978; recent reviews in Shaheen and Ransohoff, 2002; Enzinger and Mayer, 2003). It is estimated that the presence of this abnormality increases the chances of adenocarcinoma about 50-fold and that **the risk factor** is in proportion to the size of the lesion (Menke-Pluymers et al, 1993; Lagergren et al, 1999). The association of Barrett's esophagus with carcinoma is sometimes referred to as Dawson's syndrome. However, **adenocarcinomas of the esophagus may also occur in the absence of Barrett's syndrome**. The prognosis of esophageal adenocarcinoma is poor with 1-year survival

P.859

estimated at 44% but 5-year survival at only 13% (Eloubeidi et al, 2003D).

Figure 24-9 Examples of squamous carcinoma in situ from China. *A,B.* Moderately well-differentiated squamous cancer cells. *C.* Squamous carcinoma in situ in biopsy material. *D.* The site of carcinoma in situ as a reddening of mucosa in the resected segment of the esophagus. (*A,B:* High power.) (Photographs courtesy of Dr. Yi-Jing Shu, St. Gallen, Switzerland.)

Histology

Most adenocarcinomas of the esophagus occur in the area of the cardia and originate in islands of gastrointestinal mucosa, less often in the submucosal glands, and usually are histologically similar to gastric adenocarcinoma and its various histologic patterns, described below. Most tumors are well differentiated and signet ring type of carcinoma is very rare. Occasionally, papillary adenocarcinomas, composed of large columnar cancer cells, may be observed (Fig. 24-12), also possibly related to Barrett's esophagus wherein precancerous lesions of a similar histologic and cytologic type have been observed (Belladonna et al, 1974). Rubio et al (1989, 1992) observed ciliated glandular cells in dilated glands of papillary adenocarcinomas in patients with Barrett's esophagus.

As frequently happens in areas of the body where two different types of mucosa meet, tumors that have the properties of both **glandular and squamous epithelium** may occur in the lower esophagus. These cancers may be best classified as **mucoepidermoid**. There is no evidence that their behavior is in any way different from the behavior of pure epidermoid or pure mucus-producing varieties of cancer.

Precursor Lesions

The **sequence of morphologic events in the genesis of adenocarcinoma** became the subject of numerous scientific communications. Briefly summarized, **morphologic precancerous abnormalities in columnar epithelium** (named **dysplasia**, rather than **carcinoma in situ**) precede invasive carcinoma (Smith et al, 1984; Lee, 1985). These lesions **have been subdivided into "low grade" and "high grade."** The criteria of this classification have been published by Reid et al (1980) and tested as reproducible among expert pathologists by Montgomery et al (2001A).

“High-grade dysplasia” (that we would prefer to classify as **adenocarcinoma in situ**) consist of **nuclear enlargement and hyperchromasia in the columnar epithelial cells, occasionally with branching or distortion of the affected glands and a marked increase in abnormal mitoses** (Reid et al, 1988; Rubio and Riddell, 1989). The lesions are very **similar to precancerous abnormalities and carcinoma in situ of the gastric epithelium** (see Fig. 24-26). The problem with **high-grade esophageal dysplasia** is its separation from frank **adenocarcinoma, which is not**

P.860

easy either in biopsies or in cytologic samples. Prospective studies of patients with severe dysplasia indicate a high level of **progression to adenocarcinomas of the gastrointestinal type** (Smith et al, 1984; Lee, 1985; Spechler and Goyal, 1986; Rusch et al, 1994; Montgomery et al, 2001B).

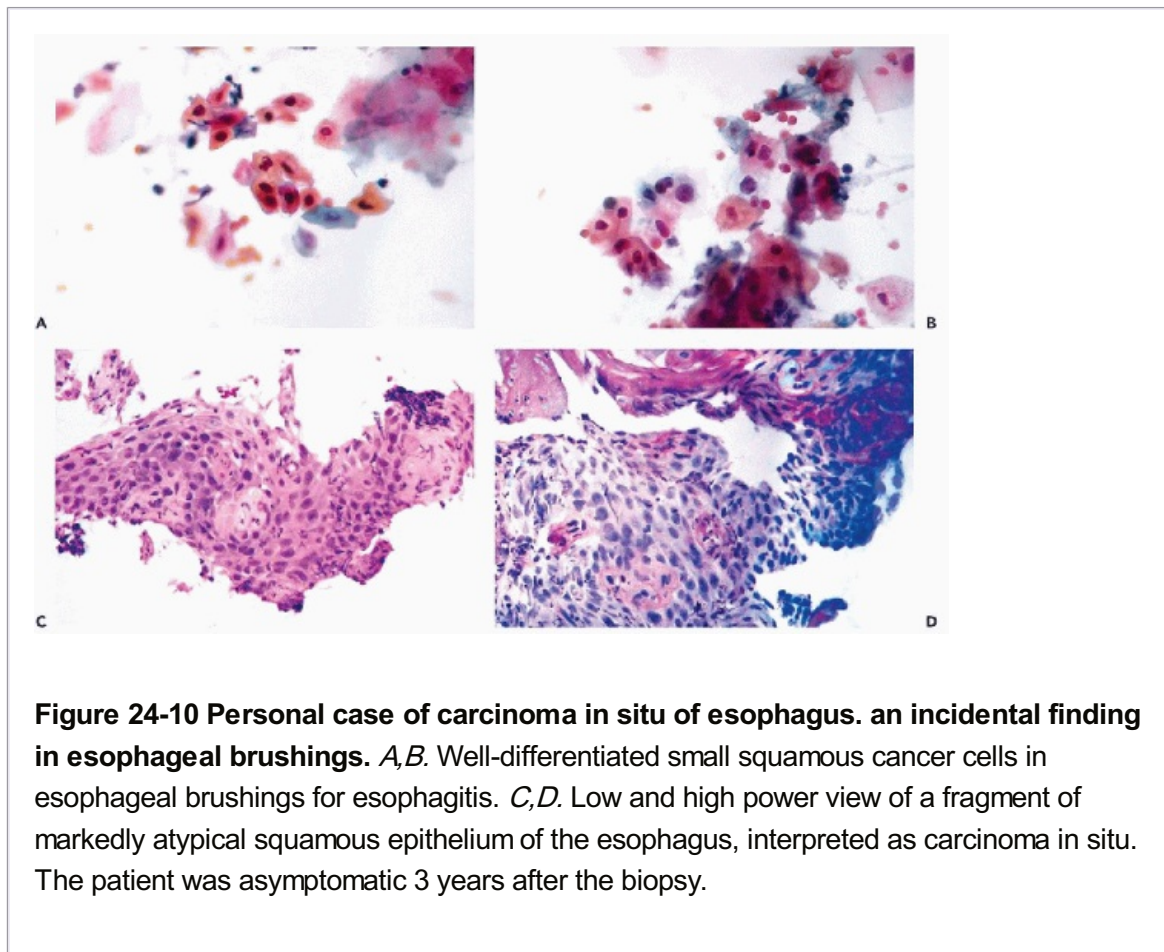

Figure 24-10 Personal case of carcinoma in situ of esophagus. an incidental finding in esophageal brushings. *A,B.* Well-differentiated small squamous cancer cells in esophageal brushings for esophagitis. *C,D.* Low and high power view of a fragment of markedly atypical squamous epithelium of the esophagus, interpreted as carcinoma in situ. The patient was asymptomatic 3 years after the biopsy.

Elaborate molecular studies suggested that high grade dysplasia and early adenocarcinoma show similar genetic alterations, regardless whether the Barrett lesion involved short or long segments of the esophagus (Nobukawa et al, 2001). Also, mutation of p53 gene was shown to be frequent in high grade dysplasia and adenocarcinoma than in low-grade dysplasia (Bian et al, 2001). Surgical resection of “severe dysplasia” is curative of the disease but it is not without major complications (Rush et al, 1994). Currently, such lesions may also be treated by endoscopic ablation, using photodynamic therapy or laser surgery (Van Dam and Brugge, 1999).

Much less secure is the identification of low grade or **“mild dysplasia”** which is described as **slight atypia of the columnar epithelial cells** (Robey et al, 1988). According to Montgomery

et al (2001A, 2001B), the diagnosis of low-grade dysplasia is fairly reproducible among expert pathologists and shows a **15% to 20% progression rate to invasive cancer**. Patients with Barrett's syndrome are monitored by endoscopic biopsies and by cytologic studies of brush specimens (Spechler, 2002).

Cytology

Invasive Adenocarcinomas and Mucoepidermoid Carcinomas

In brush specimens, the cancer cells derived from adenocarcinomas are usually **well-differentiated columnar cells with conspicuous nuclear abnormalities in the form of enlarged, sometimes hyperchromatic nuclei with large single or multiple nucleoli** (Fig. 24-12A,C). In advanced carcinomas, **these cells occur singly and in small clusters, usually accompanied by evidence of necrosis**. Smaller, more spherical cancer cells may also occur in less well-differentiated tumors. Shurbaji and Erozan (1991) noted that the findings were not consistent and that nuclear hyperchromasia and large nucleoli were not observed in all the cases.

In **mucoepidermoid carcinomas**, the cells of glandular derivation are **mixed with occasional squamous cancer cells**. In many such cases, it is not clear **whether the tumor is primarily squamous or glandular**, although the malignant nature of the process is evident.

Precursor Lesions

Cytologic definition of "dysplasia" of columnar epithelium is insecure. Wang et al (1992) described **small clusters**

P.861

of mildly pleomorphic cells with enlarged nuclei with occasional multiple nucleoli. In a more recent thoughtful review of this topic by Hughes and Cohen (1998), the definition of cytologic abnormalities in dysplasia was not particularly helpful. These authors reviewed the literature and pointed out that the accumulated experience with comparative cytology-histology of these lesions is very small.

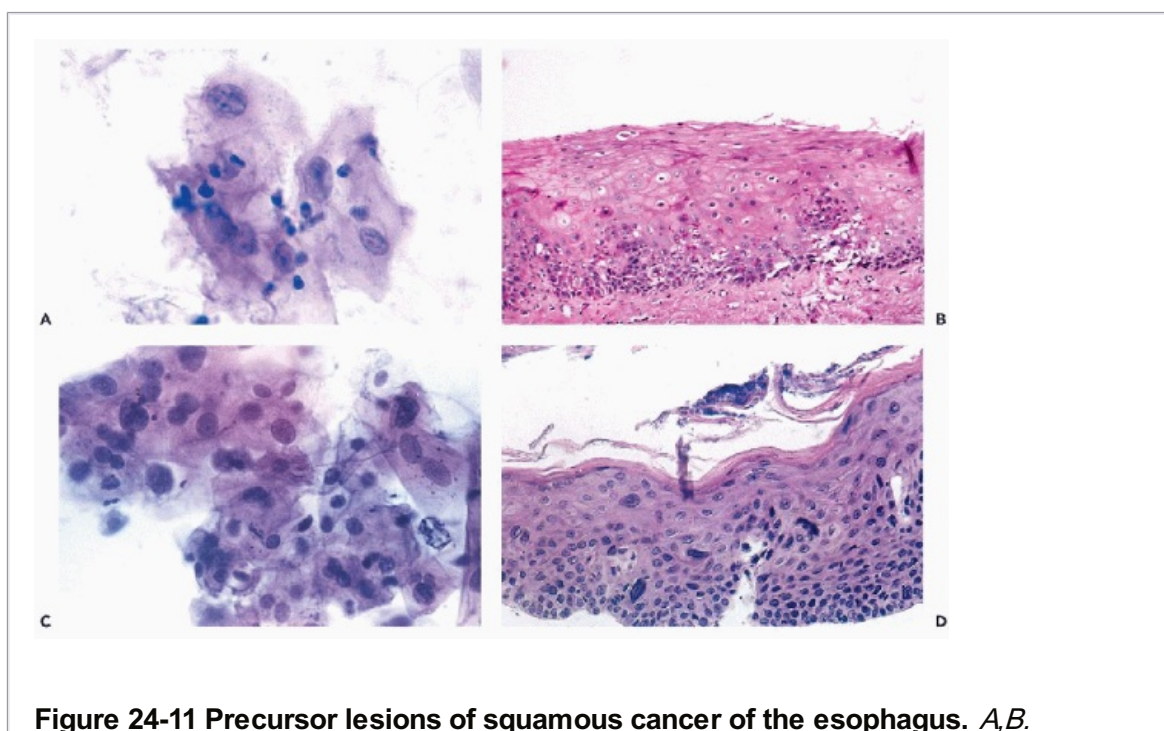

Figure 24-11 Precursor lesions of squamous cancer of the esophagus. A,B.

Precancerous lesion of the esophagus classified as “mild dysplasia.” *A*. Superficial dyskaryotic (dysplastic) squamous cells corresponding to the tissue lesion shown in *B*, which shows only mild focal abnormalities of the squamous epithelium. *C,D*. Precancerous lesion of the esophagus classified as “moderate dysplasia.” The balloon smear shown in *C* shows well-differentiated parabasal squamous cancer cells. *D*. The biopsy of the same lesion shows moderate to marked nuclear abnormalities within the squamous epithelium. The lesion shown in *C* and *D* could be classified as high rather than low-grade. (Photographs courtesy of Dr. Yi-Jing Shu, St. Gallen, Switzerland.)

Personal experience suggests that the **morphologic distinction of “high-grade or severe dysplasia” from adenocarcinoma is highly subjective**. In cases with **clusters** of mildly or moderately atypical columnar cells with **somewhat enlarged, somewhat hyperchromatic nuclei and the presence of multiple small or single large nucleoli**, the diagnosis of **“atypia” of columnar cells** is justified (Fig. 12-13A,B). **If the atypical cells form clusters, the possibility of an adenocarcinoma cannot be ruled out** (Fig. 12-13C,D). **In all such cases**, the tentative cytologic diagnosis **must be confirmed by biopsies**. The situation is reminiscent of the problems with recognition of early neoplastic abnormalities in endocervical epithelium, discussed at length in Chapter 12.

There is virtually no cytologic experience with the identification of **“mild dysplasia.”** Hughes and Cohen (1998) point out that the separation of the possible neoplastic from reactive changes in the columnar cells is virtually impossible.

Monitoring of precursors of adenocarcinoma by balloon cytology was attempted with diverse results. Fennerty et al (1995) failed to obtain informative samples in a small number of patients. Falk et al (1997), in a much larger series of patients, **compared the inexpensive balloon cytology with brushings**. Brush cytology recognized all of 11 patients with high-grade dysplasia and carcinoma whereas balloon samples failed to recognize two of these patients. For **low-grade dysplasia, both brushings and balloon cytology failed in a substantial proportion of cases**. In two of the patients without disease, atypical cells were observed. This study documented the problem with cytologic diagnosis of low-grade abnormalities.

The monitoring of **epithelial DNA content by flow cytometry** disclosed abnormal, aneuploid DNA histograms in dysplasias and in carcinomas (Haggitt et al, 1988). However, securing adequate cell samples for this procedure by esophageal brushings is difficult. Another approach to progression of dysplasia to adenocarcinoma in tissue samples was discussed by Polkowski et al (1995). These authors reported an

P.862

increase in the expression of mutated p53 gene and an increase in the proliferative fraction of cells as measured by expression of Ki67 antigen with progression of esophageal dysplasia to adenocarcinoma. To our knowledge, this approach has not been tested in cytologic samples.

Figure 24-12 Adenocarcinoma of esophagus. *A.* Composite picture of columnar cancer cells in a case of esophageal adenocarcinoma shown in *B.* *C.* Very large columnar cancer cells in another case of esophageal adenocarcinoma in a 43-year-old man without evidence of Barrett's syndrome. The tissue lesion corresponding to *C* is shown in *D.*

CYTOLOGIC FOLLOW-UP OF PATIENTS WITH TREATED ESOPHAGEAL CARCINOMA

The customary treatment of invasive carcinoma of the esophagus is either by surgery, radiotherapy alone or by radiotherapy followed by an attempt at surgical removal of the lesion. Extensive surgical resection for esophageal adenocarcinoma did not improve the survival rate (Hulscher et al, 2002). Combining chemotherapy with cisplatin and radiotherapy (**chemoradiotherapy**) did not improve overall survival of patients (Bosset et al, 1997). In several cases so treated, the observation has been made that, **in spite of the remarkable clinical improvement following radiotherapy, the smears remained positive.** In several of the surgically removed esophagi, there was **disappearance of much of the invasive tumor, but areas of carcinoma in situ were not affected by therapy.** This situation is reminiscent of the results of radiation treatment of carcinoma of the bladder, discussed in Chapter 23. Undoubtedly, the persisting carcinomas in situ are at the origin of treatment failure in many cases. Stockeld et al (2002) used **serial needle aspiration biopsies** of various parts of the esophagus to rule out the presence of **occult foci of cancer.** The presence of cancer cells in areas of the esophagus grossly free of tumor correlated with poor prognosis.

Brien et al (2001) described **gastric dysplasia-like** epithelial atypia associated with chemoradiotherapy of esophageal cancer. For further discussion of gastric dysplasia, see below.

Radiation changes observed in esophageal cytologic material are closely similar to those described for the uterine cervix (see Chapter 18) and the respiratory tract (see Chap. 19) (Fig. 24-14). The changes may affect both benign and malignant cells (Cabr  -Fiol, 1970). **The diagnosis of persisting or residual carcinoma should be made only on cancer cells showing no effect of radiation.**

Radiomimetic changes in esophageal epithelium were described by O'Morchoe et al (1983) in patients receiving **cytotoxic drug therapy** for tumors other than esophageal cancer. Some of these patients also had **herpetic esophagitis** and infections with fungi of the ***Candida* species**.

P.863

EFFECTIVENESS OF CYTOLOGY IN THE DIAGNOSIS OF ESOPHAGEAL CANCER

The effectiveness of balloon cytology in the detection of precancerous lesions of the esophagus has been documented in the studies from the People's Republic of China, cited above.

The contributions of cytology in symptomatic patients before widespread use of fiberoptic instruments are best assessed by comparison with other diagnostic techniques: a few **cases of esophageal carcinoma with negative radiographic findings were observed in this laboratory**. The results, of historical interest only, were reported from our laboratory and Papanicolaou's laboratory by Johnson et al in 1955. The cytologic results in 148 cases of esophageal cancer and 135 controls are summarized in Tables 24-1 and 24-2. **In a significant percentage of cases (12%), cytology yielded positive results, whereas the biopsy was either negative or impossible to obtain.** We also reported **three false-positive cases**, based on the presence of atypical squamous cells in cases of erosive esophagitis (see above).

Other older studies (Raskin et al, 1959; Prolla and Kirsner, 1972; Cabré-Fiol, 1970; Drake, 1985) also show a very high rate of accuracy in the diagnosis of esophageal carcinoma, ranging from 90% to 95%. It is of interest that the introduction of fiberoptics and of direct

brushing resulted in only slight improvement in the accuracy of cytologic diagnoses of esophageal cancer, when compared with the simpler methods of washings and aspirations. Geisinger (1995) compared the results of cytologic **brushings** with **endoscopic biopsies** in specimens from a broad spectrum of esophageal diseases. There were 18 carcinomas, of which 9 were squamous and 6 adenocarcinomas. In 3 of the 18 carcinomas the diagnosis was established by cytology with negative initial biopsies. One squamous cancer was missed by cytology. Geisinger provided a summary of findings from several papers on this topic. The superiority of brush cytology over biopsies in the diagnosis of esophageal cancer was repeatedly confirmed, thus documenting the clinical value of cytologic techniques.

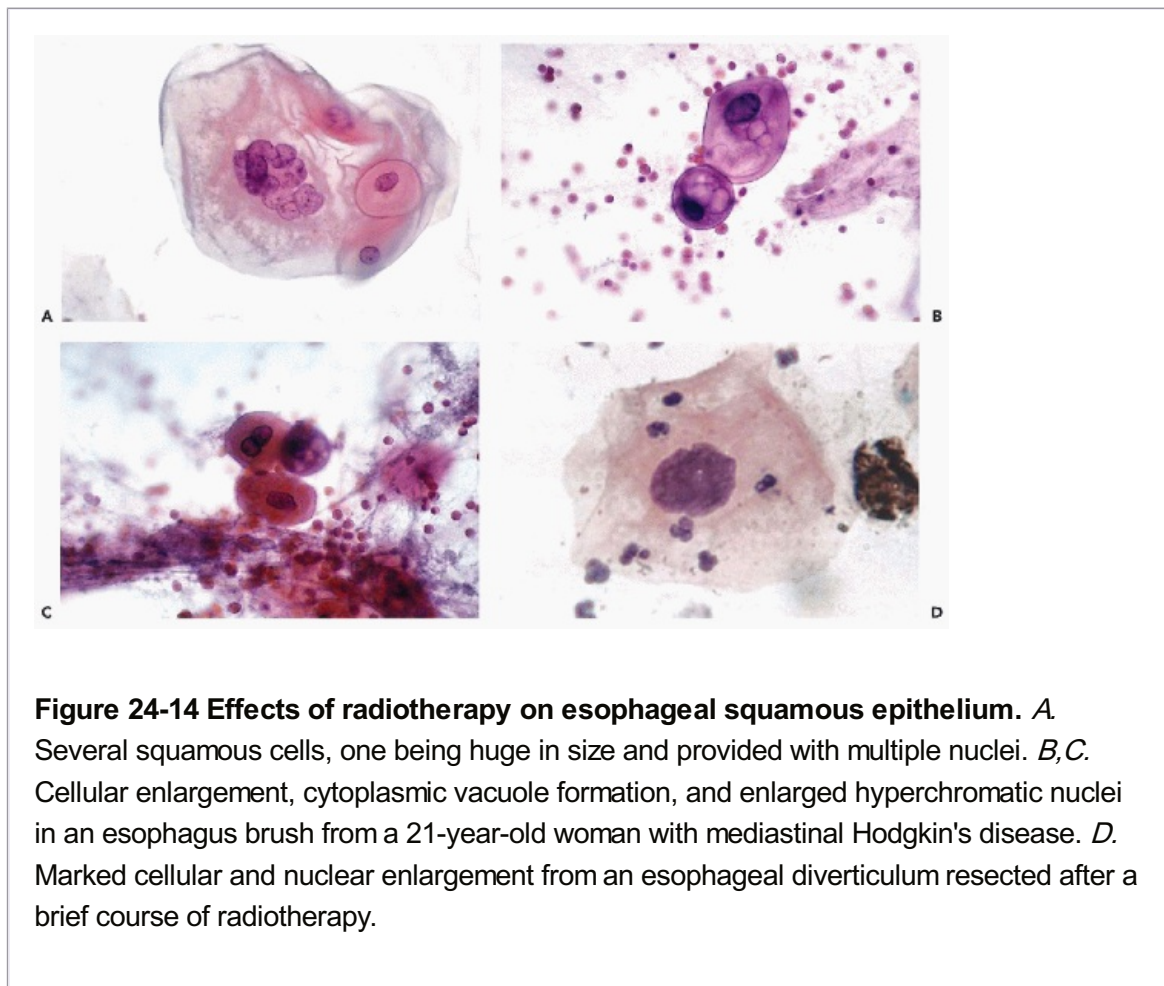

RARE MALIGNANT TUMORS OF THE ESOPHAGUS

Adenoid Cystic Carcinoma

We have seen one example of this lesion which is most unusual in the esophagus. The tumor has been described in reference to salivary glands and the bronchus (see Chaps. 20 and 32). As is the case in other organs where the tumor is more common, the brush smear disclosed **clusters of small, monotonous**

P.864

cancer cells with fragments of homogeneous, hyaline material, corresponding to the basement membrane material contained within the cystic spaces in the tumor.

Carcinoma with Pagetoid Changes

An exceptional event is the presence of **pagetoid change** that has been observed in the

esophageal epithelium adjacent to areas of carcinoma, reported by Yates and Koss (1968). The invasion of the squamous epithelium by large, clear cells of adjacent carcinoma resulted in this readily identifiable histologic pattern, similar to that occurring in the epithelium of the nipple or vulva in Paget's disease (see Chaps. 15 and 29). In the case illustrated here, the **cancer cells shed from the pagetoid area were approximately spherical, had a clear cytoplasm, and were occasionally**

P.865

arranged in the cell-in-cell pattern, whereas the cells from the main bulk of the tumor were poorly differentiated (Fig. 24-15).

TABLE 24-1 RESULTS OF CYTOLOGIC EXAMINATION OF THE ESOPHAGUS

	Total Cases	Cytology		
		Positive	Suspicious	Negative or Insufficient
Malignant tumors primary in esophagus	148 (100%)	103 (70%)	18	27
No malignant tumor	135	3*	7	125

* Three cases of esophagitis.

(Johnson WD, et al. Cytology of esophageal washings: evaluation of 364 cases. Cancer 8:951-957, 1955.)

TABLE 24-2 COMPARISON OF RESULTS OF CYTOLOGIC EXAMINATION WITH RESULTS OF BIOPSY IN 148 PRIMARY CANCERS OF ESOPHAGUS

	Total Cases	Cytology		
		Positive	Suspicious	Negative
Biopsy				
Positive	117	85	14	18
Negative	18	11	2	5
Impossible to obtain	13	7	2	4
Total	148	102	18	27

(Johnson WD, et al. Cytology of esophageal washings: evaluation of 364 cases. Cancer 8:951-957, 1955.)

Polypoid Carcinoma (Carcinosarcoma)

Histology

Uncommonly, squamous carcinomas of the esophagus (but also of the larynx, pharynx, and rarely in the vagina) develop into **polypoid bulky tumors, the surface of which is formed by a well-differentiated epidermoid carcinoma, sometimes in situ. The bulk of the tumor is composed of elongated spindly cells, occasionally accompanied by bizarre giant cells** (Enrile et al, 1973). Experience with these lesions suggests that the spindle and giant cell components represent a peculiar metaplasia of squamous carcinoma and not a benign "pseudosarcoma," as was originally suggested by Stout and Lattes (1957). Still, the latter term is often used to describe this lesion. It must be stressed that, in spite of its ominous appearance, the polypoid carcinoma appears to offer a much better prognosis than ordinary esophageal carcinoma.

Cytology

The cytologic findings in brushings from one of the rare polypoid carcinomas of the esophagus were described by Selvaggi (1992). The smears contained **cells of squamous carcinoma and spindly cancer cells, and a few multinucleated giant cells, corresponding exactly to the histologic make-up of the tumor.** We observed a similar tumor in the **vagina**. The smears were composed of malignant squamous cells only (see Chap. 17).

Malignant Melanoma

Several case reports of the very rare **primary esophageal melanoma** were published (Bullock et al, 1952; Boyd et al, 1954; Broderick et al, 1972; Chaput et al, 1974; Ludwig et al, 1981), occasionally associated with melanosis (De la Pava et al, 1963; Piccone et al, 1970). Summaries of the subject were presented by Mills and Cooper (1983) and by Kanavaros et al (1989). Broderick et al (1972) reported a case of **esophageal melanoma with cytologic diagnosis**. The **malignant cells were clearly pigmented** and, accordingly, the accurate diagnosis could be readily established. A similar case was reported by Aldovini et al (1983). One of these very infrequent tumors of the esophagus was diagnosed cytologically by us as cancer but, in the absence of pigment, it was thought to be an epidermoid carcinoma. De la Pava et al (1963) described **pigmentation of normal esophageal epithelium as melanosis**. This extremely rare condition could be a source of diagnostic error. However, Piccone et al (1970) and Kanavaros et al (1989) described a **malignant melanoma developing in melanosis**, thus complicating the issue still further.

Sarcomas

Sapi et al (1992) described the cytologic findings in a polypoid tumor of the esophagus, classified as **malignant fibrous histiocytoma** on the strength of immunocytologic and ultrastructural findings. The smears were characterized by the presence of **bizarre tumor giant cells**. Clearly, the differential diagnosis in such cases must include polypoid carcinomas, discussed above.

A rare case of **rhabdomyosarcoma** of the esophagus was described by Shah et al (1995). A case of **embryonal rhabdomyosarcoma** was described by Willen et al (1989). The cytologic presentation of similar tumors in other organs was described in Chapters 23 and 26.

Choriocarcinoma

A case of an exceedingly rare primary choriocarcinoma of the esophagus was described by Trillo et al (1979). The cytologic features of this tumor are described below in the section on rare gastric tumors, in Chapter 17, discussing rare tumors of the female genital tract, and in Chapter 23, discussing rare tumors of the urinary bladder.

P.866

Figure 24-15 Carcinoma at the junction of cardia and esophagus with pagetoid changes in the adjacent esophageal epithelium. *A.* Cluster of poorly differentiated cancer cells (esophageal washings). *B.* Elsewhere in the smear isolated, large cancer cells with clear cytoplasm were noted. *C.* The surgical specimen disclosed a carcinoma of the cardia extending into the esophagus. *D.* The squamous epithelium of esophagus at the edge of the tumor disclosed a typical pagetoid change with large cells with clear cytoplasm.

THE STOMACH

ANATOMY

The stomach is a pouch situated between the esophagus and the duodenum, immediately below the diaphragm; it forms a reservoir of variable capacity within which the preliminary stages of digestion take place. The stomach is divided anatomically into several regions, starting at the esophageal end: the **cardia** (the orifice between the stomach and the esophagus and the adjacent portion of the stomach), a lateral bulge or the **fundus**, the more distal portion

of the stomach or **the body**, and the most distal **pyloric area (antrum)**, which is separated from the duodenum by a powerful ring of smooth muscle, the **pylorus**. Obstruction of the gastric lumen may occur at either end of the stomach—the cardia or the pylorus (see Fig. 24-1).

From inside out, the stomach is lined by an **epithelium (mucosa)**, described in detail below, a **lamina propria**, composed of connective tissue and a thin layer of smooth muscle (**muscularis mucosae**), a powerful layer of smooth muscle or the **muscularis propria**, and the outer layer or the **serosa**, lined by the peritoneum.

HISTOLOGY OF GASTRIC EPITHELIUM (MUCOSA)

Gastric epithelium is by far the most important component of cytologic preparations. The gastric mucosa is composed of **simple tubular glands**. The **lining of the glands of the fundus and the body** of the stomach is complex: the **surface and the necks of the glands are lined by mucus-producing cells**. The **deeper portions of the glands contain pepsin-producing chief cells and the eosinophilic parietal cells** that produce hydrochloric acid. The hydrochloric acid is excreted through microscopic canaliculi passing between the chief cells. The **gastric glands of the pyloric area are** fairly uniformly lined by **mucus-producing cells** (Fig. 24-16A).

Electron microscopic studies revealed distinct differences between the cells lining the gastric surface and those lining the neck of the glands. Both cells are mucus-producing but they differ in the type of secretory granules, thus probably performing somewhat different functions. The ultrastructure of the parietal cell fails to reveal any secretory activity. The pepsin-producing chief cells resemble somewhat the exocrine pancreatic and salivary gland cells inasmuch as they contain cytoplasmic secretory granules and

P.867

an abundant rough-surfaced reticulum. Argentaffin cells containing dense cytoplasmic granules may be observed in some of the crypts.

Figure 24-16 Normal stomach. *A.* Configuration of normal gastric epithelium (see text). *B.* Benign columnar gastric cells in gastric brushes. *C.* Sheet of benign gastric cells showing

the “honeycomb” configuration. *D.* Tall mucus-producing cells from a case of intestinal metaplasia. (*B*: Composite photograph obtained with the PAPNET apparatus. With the permission of TriPath Imaging, Burlington, NC.)

CYTOLOGY OF NORMAL STOMACH

The make-up of the specimens varies **according to the method used** to collect the material. **Gastric lavage**, extensively used by Schade and his co-workers (1956A,B, 1959, 1960A,B), yields few normal gastric cells. The **gastric balloon with a rough surface**, devised by Panico et al (1950, 1952) to improve the collection of gastric epithelial cells, yields a richer harvest of cells. The optimal samples of gastric epithelium are obtained by **gastric brushings** during fiberoptic gastroscopy.

In the absence of disease, normal gastric epithelium in brush specimens is represented by columnar cells, occurring singly or forming **cohesive fragments of cells with opaque or clear cytoplasm**. The columnar configuration of the component cells is seen at the edge of such clusters, whereas the center of the cluster shows the “honeycomb” pattern (Fig. 24-16B,C). The **relatively uncommon, mucus-producing columnar cells** display an abundant, **clear cytoplasm** and have one **flattened surface**, corresponding to the gastric lumen, whereas the **opposite end usually tapers off in the form of a tail** (Fig. 24-16D). Raskin et al (1961) pointed out that such **cells originate from the area of the pyloric antrum**. Such cells are common in **intestinal metaplasia** of the gastric mucosa (see below).

A “**wheel-spokes**” arrangement of single cells, with their “tails” directed toward the center may be observed. **Tubular structures** representing entire glands removed by vigorous brushing may also be encountered.

The nuclei of normal gastric cells are located in the approximate **center of the cells**. They are usually spherical, of equal sizes, clear or somewhat opaque, and contain a few granules of chromatin and occasionally a noticeable but very small pink nucleolus. In mucus-producing columnar cells, **the nuclei may be displaced toward the distal end of the cell, a position also observed in goblet cells that play an important role in intestinal metaplasia** (see below). Occasionally, **dense nuclear protrusions**, similar to those observed in endocervical cells, can be observed (see

P.868

Chap. 8). When the cytoplasm of the gastric cells is destroyed during processing of the specimens, “**naked**” nuclei or **nuclei surrounded by cytoplasmic shreds** may be numerous. In **cell blocks**, small fragments of gastric epithelium may occasionally be identified.

Using rapidly fixed material and Papanicolaou stain, **we have not been able to identify with certainty the parietal and the zymogenic (chief) cells** in the smears of gastric specimens. However, Henning and Witte (1957), using air-dried specimens and Pappenheim stain, described the **chief cells** as **plump cells, containing numerous coarse basophilic granules in the cytoplasm**; the **parietal cells** were described as **small cylindrical cells with a very marked vacuolization of the cytoplasm**. Nieburgs and Glass (1963) identified the chief cells as “darkly stained cells of intermediate size” in brush specimens. Granules were not demonstrated in Papanicolaou stain. The parietal cells were identified by the same authors as “large, pale, round or triangular cells,” and, thus, their description is at variance with that given by Henning and Witte, but more in keeping with the histologic appearance of these cells.

Takeda (1983) also described the **parietal cells as triangular cells with granular cytoplasm**.

In gastric specimens obtained by **aspiration or washings, swallowed cells of the respiratory and the upper alimentary tract are sometimes present. Ciliated respiratory cells, dust-containing macrophages, and squamous cells of buccal and esophageal origin** may be observed. Also, in the presence of gastric obstruction, **food particles** and, in particular, plant (vegetable) cells, may contaminate the specimen, occasionally rendering it totally useless (see Chap. 19 for detailed description of plant cells).

Other cells present in normal gastric specimens include **sparse polymorphonuclear leukocytes and lymphocytes**. Recognizable **macrophages** may be noted.

BENIGN GASTRIC DISORDERS

Parasites

The flagellated parasite ***Giardia lamblia*** has been recognized as a common cause of infection of the small intestine and may sometimes be seen in gastric cytology specimens. Symptoms vary from mild to severe gastrointestinal disturbances. *Giardia lamblia* has two stages: cysts and protozoa. The cysts, transmitted in drinking water or by person-to-person contact, are the source of infection. The protozoa, which are released from the cysts, can be recognized in gastric smears as a **flat, pear-shaped small organism, with four pairs of flagella and two nuclei that mimic the appearance of eyeglasses** (Fig. 24-17A). Bloch et al (1987) observed the parasite in the **peritoneal fluid** of a patient with severe infestation.

Trophozoites of the ***Acanthamoeba* species**, probably a contaminant, were observed by Hoffler and Rubel (1974).

Fungi and Viruses

In patients with AIDS, gastric samples may contain evidence of fungal infection, such as **moniliasis**, which is usually also present in the esophagus. ***Cytomegalovirus*** infection of gastric epithelium is the most common viral infection and may be associated with **gastric ulcers** (Fig. 24-17B). Other organisms, such as ***Helicobacter pylori*** are discussed below.

Gastritis and Gastric Ulcer (Type B Gastritis)

Inflammation of the gastric mucosa is a common disorder that may lead to gastric ulceration and may be related to gastric cancer. In 1947, Schindler proposed a subdivision of gastritis into **acute** and **chronic**. In 1990, an attempt was made to standardize the nomenclature of gastritis at a meeting of experts in Sydney, Australia (Price, 1991). The purpose of the **Sydney classification** was to integrate histologic, microbiologic, and endoscopic data to render the classification of gastritis more reproducible.

The reproducibility of histologic classification of gastritis in biopsies is still not optimal (Guarner et al, 1999). These problems cannot be solved by **cytology of the gastric epithelium** which serves mainly to differentiate an inflammatory process from cancer.

Pathogenesis

Until the 1980s, the causes of acute gastritis and of gastric or duodenal ulcer were not clearly understood. Some drugs, such as **lithium**, were shown to be occasionally associated with gastritis. In 1983, an anonymous observation was reported in the journal *Lancet*, suggesting

that a not-furtheridentified bacterium may be associated with gastritis. The observation was confirmed by Marshall and Warren in 1984. The infection with this bacterium, now known as ***Helicobacter pylori*** (previously known as ***Campylobacter pylori***), is very common. The source of the bacterium is drinking water, soil, flies etc. (Sasaki et al, 1999; Suerbaum and Michetti, 2002). Two strains of the bacterium have been sequenced. It is believed that the **bacterial genes can affect human genes encoding cell membrane adhesion molecules** (Ge and Taylor, 1999). Amieva et al (2003) have shown that the bacterium is capable of disrupting the apical tight junctions binding gastric cells. ***H. pylori*** has now been recognized as the main cause of acute gastritis (also known as pyloric or type B gastritis), ulcer disease, and colitis (Goodwin et al, 1986; Blaser, 1987; Dooley et al, 1989; Cover and Blaser, 1996; Bodger and Crabtree, 1998). There appears to be a relationship between ***H. Pylori*, gastric cancer and malignant lymphomas of the mucosa-associated lymphoid tissue (MALT lymphomas)** (see below).

A related organism *Gastrospirillum hominis* (previously known as *Helicobacter heilmannii*) has been recognized as a less frequent cause of a milder form of chronic gastritis. The two organisms share many pathologic features but have some morphologic differences. *H. pylori* forms **gram-negative curved rods** about 3 µm in length and 0.5 µm in width (Fig. 24-17C,D). *G. hominis* is somewhat longer (3.5 to 7.5 µm), tightly coiled, and can be recognized as straight, spirochete-like structures (summary in Rotterdam et al, 1993).

Both organisms can be identified in **Papanicolaou-stained**

P.869

cytologic samples but are much easier to demonstrate in Warthin-Starry silver impregnation or by Giemsa stain and its modifications (Taylor et al, 1987; Davenport, 1990; Pinto et al, 1991; Mendoza et al, 1993; Ghossoub and Lachman, 1997). Several observers suggested that the organism may be easier to identify in smears prepared from gastric biopsies than in tissues sections (Faverly et al, 1990).

Figure 24-17 Inflammatory gastric disorders. A. *Giardia lamblia* in gastric lavage. Note the triangular configuration of the parasites with the characteristic two-nuclei mimicking eyeglasses. B. Cytomegalovirus in a gastric ulcer. The presence of the virus was documented by a specific antibody. C,D. *Helicobacter pylori*. Minuscule corkscrew

organisms are seen in the background of the gastric biopsy in *C* and in a gastric brushing in *D* (arrows). (*C*: High power; *D*: oil immersion.)

Chronic Gastric Peptic Ulcer

Clinical Data

Gastric ulcer is a common disease, occurring in patients of all ages, but usually in adults. Most patients have an increased gastric acidity and *Helicobacter pylori* infection. Feared **complications of gastric ulcer include massive gastric hemorrhage and perforation of the gastric wall.** Quite often, particularly when these lesions are small and superficial, the **clinical and radiographic or endoscopic differential diagnosis between a gastric carcinoma and a chronic peptic ulcer may be extremely difficult.** Therefore, these lesions are the **prime target of endoscopic and cytologic studies** (Cantrell, 1971; Prolla et al, 1971; Prolla and Kirsner, 1972).

Histology

Chronic peptic ulcer is an **inflammatory defect in the gastric epithelium** extending for a variable depth into the submucosa and even the muscularis and beyond. The ulcer often undermines one edge of the adjacent epithelium. Depending on the chronicity of the disease, the tissues surrounding the ulcer bed may show **varying degrees of chronic inflammation and fibrosis.** Occasionally, large aggregates of lymphocytes and plasma cells may be noted. **The epithelium surrounding the ulcer shows various degrees of hyperplasia and regeneration.** In the latter case, marked mitotic activity and atypia may be present (Fig. 24-18A,B). There is considerable debate whether gastric carcinoma may develop in peptic ulcer epithelium. Cases do occur wherein this possibility is strongly suggested by histologic findings.

Cytology

Gastric cytology and endoscopic biopsies are the prime methods of differential diagnosis between benign ulcer and carcinoma. Regardless of the technique used to sample the gastric epithelium, the cytologic specimens usually contain **many clusters of gastric epithelial cells.** Necrotic material, fibrin, and inflammatory cells, such as neutrophils or lymphocytes, are usually present in the background. **Cell debris and isolated ("naked") nuclei may be abundant.**

P.870

Figure 24-18 Gastric ulcer and gastric repair. *A.* A characteristic crater of a gastric ulcer with its fundus occupied by a fibrin clot. *B.* Gastric biopsy showing atypical proliferation of glands with mitotic activity at the edge of a gastric ulcer. *C,D.* Cells from gastric repair forming a sheet in *C* and appearing singly in *D*. The cells are characterized by the presence of clearly visible nucleoli.

As is the case in other “repair” reactions, the changes in the gastric epithelial cells in peptic ulcers may be difficult to interpret. Flat clusters of cells, arranged side-by-side, are the dominant feature, whereas single cells are relatively few in number (Fig. 24-18C,D). In brush specimens, this important relationship of cells to each other cannot always be fully appreciated because the cell clusters may be thick and unfit for detailed visual analysis. However, the cells at the periphery of such clusters usually are suitable for inspection.

The morphologic features of gastric epithelial cells in ulcer disease are best appreciated in small clusters or in single cells. The cells are **polyhedral rather than columnar** and their **cytoplasm is often opaque**. The principal difficulty in the interpretation of this material is with the **nuclei which are usually enlarged, clear or opaque, and dark, and may contain one or more nucleoli of various sizes** (Fig. 24-18C,D). Drake (1985) stressed nuclear enlargement as a common feature of cells in chronic gastric ulcer and we can confirm his observation.

When conspicuous nuclear and nucleolar enlargement is present in epithelial cells, the differential diagnosis among chronic inflammatory disease, gastric carcinoma, and precancerous abnormalities (both discussed below) becomes exceedingly difficult. The presence of flat cohesive clusters and few single epithelial cells, the absence of significant variability in nuclear sizes, and regular and smooth nuclear membrane are in favor of an inflammatory process, but these criteria are not always helpful. The problem is compounded because occasional gastric carcinomas shed cancer cells with only modest nuclear abnormalities. In such fortunately uncommon cases, the degree of histologic abnormality in a biopsy may also present a diagnostic dilemma that is best solved by additional sampling.

Diagnostic misinterpretation of cytologic findings as cancer in extreme cases of gastric atypia

occurs even among observers who combine vast clinical and laboratory experience and thus are best qualified to avoid such mistakes. Prolla and Kirsner (1972) cite five such false positive mistakes among 2,196 patients with benign gastric disease (0.05%).

“Aspirin” Gastritis

Difficult to interpret cytologic abnormalities, similar to those observed in chronic gastric ulcers, may occur in users of **aspirin** and **newer analgesic drugs** who are prone to **erosions of gastric mucosa with episodes of hematemesis**. **Patients with rheumatoid arthritis** appear to be at significant risk, presumably because of long-term use of large doses of these drugs. In biopsies of the hemorrhagic areas, there

P.871

is often superficial erosion of the surface epithelium. In more chronic cases, the superficial ulceration may be accompanied by a marked disruption of the mucosal architecture. The glands vary in size and shape and are arranged in a disorderly pattern. The cells lining the **glands, particularly in the deeper portion of the gastric epithelium, show marked abnormalities, such as nuclear enlargement, hyperchromasia, and mitotic activity** (Fig. 24-19A).

Cytology

Cell samples obtained by brushing may show conspicuous abnormalities (Fig. 24-19B-D). The gastric epithelial cells may form **clusters or strips wherein there is variability of nuclear sizes and hyperchromasia of individual nuclei**. Some cells containing **large nucleoli may suggest a gastric carcinoma**. Similar nuclear abnormalities may be observed in columnar or cuboidal **dispersed single cells**. Perhaps the **most disturbing cytologic finding is the presence of clusters of dark nuclei, stripped of cytoplasm**. In the third edition of this book (1979), it was felt that the differential diagnosis of aspirin gastritis from carcinoma was not possible in the absence of clinical history. This view may be somewhat modified today. Although cell clusters may strongly suggest a malignant tumor, the **abnormalities in the single cells, essential to confirm the diagnosis, do not quite measure up to cancer**: the degree of nuclear changes and the size and variability of the nucleoli are less conspicuous than in cancer, but, admittedly, these may be personal perceptions, not easily duplicated.

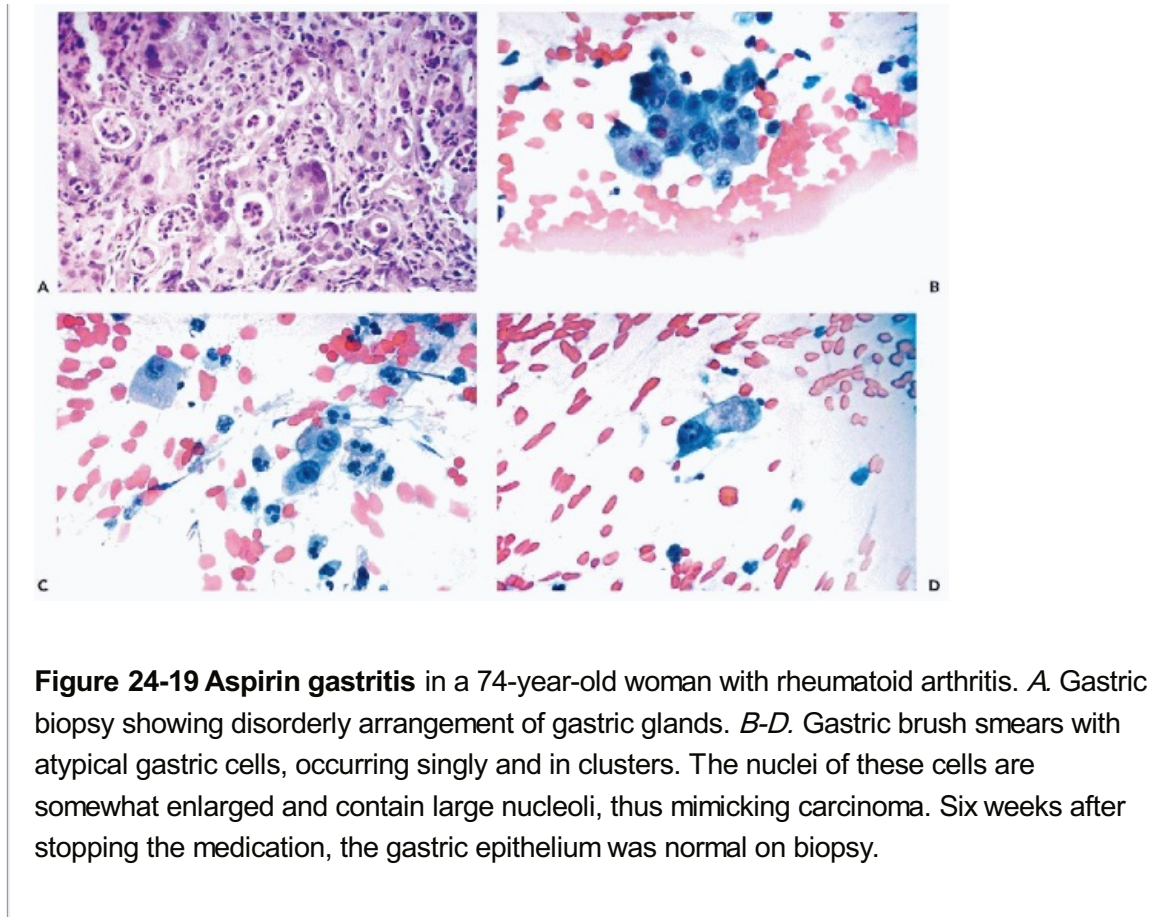

Figure 24-19 Aspirin gastritis in a 74-year-old woman with rheumatoid arthritis. *A*. Gastric biopsy showing disorderly arrangement of gastric glands. *B-D*. Gastric brush smears with atypical gastric cells, occurring singly and in clusters. The nuclei of these cells are somewhat enlarged and contain large nucleoli, thus mimicking carcinoma. Six weeks after stopping the medication, the gastric epithelium was normal on biopsy.

An accurate **clinical history of analgesic intake may prevent the erroneous diagnosis of gastric carcinoma**. This is particularly important because, within a few weeks after **discontinuation of analgesics, the gastric epithelium recovers** and returns to normal.

Chronic Atrophic Gastritis (Type A Gastritis) and Intestinalization of the Gastric Mucosa

Pathogenesis

Atrophy of gastric epithelia and the replacement of normal gastric epithelium by cells akin to those of mucus-producing epithelium lining the large intestine (**intestinal metaplasia or intestinalization**) usually occur together in the **distal portion of the stomach**. Loss of gastric folds and an **inflammatory infiltrate consisting of lymphocytes and plasma cells in the mucosa and submucosa** are common findings in this disorder which may be observed in a variety of chronic inflammatory conditions and in pernicious anemia.

P.872

Contrary to gastritis type B, described above, ***H. pylori* is absent** and does not appear to play a role in the genesis of atrophic gastritis which is now considered to be an **autoimmune disease** (Toh et al, 1997).

The significance of intestinal metaplasia as a precancerous event has been studied morphologically (Morson, 1955) and by epidemiologic analysis of gastric cancer-prone populations (Correa, 1982; Rubio et al, 1987; Correa and Chen, 1994). The consensus has developed that, **in populations with a high rate of intestinal metaplasia, there is also a high rate of gastric carcinoma of intestinal type** (see below).

Histology

Intestinal metaplasia consists of large, tall, mucus-producing cells, replacing normal gastric epithelium. The mucus-producing cells are often referred to as goblet cells but are morphologically somewhat different. The metaplastic epithelium also contains **Paneth cells with granular and eosinophilic cytoplasm**, which cannot be identified with reliability in cytologic material. Rubio and Antonioli (1988) reported rare cases of **intestinal metaplasia with ciliated cells**.

Cytology

The condition may be recognized occasionally in cytologic material, which may contain **mucus-producing columnar epithelial cells larger than the normal gastric cells and provided with an abundant, clear cytoplasm** (see Fig. 24-16D). These cells are **more slender than goblet cells** and closely **resemble normal columnar cells desquamating from the colonic mucosa** (see below). **The nuclei are round and even, but are sometimes somewhat larger and darker than normal.** The recognition of intestinal metaplasia in cytologic material is of limited diagnostic significance, except as a warning that the patient may be at risk for gastric carcinoma.

Gastric Tuberculosis

Gastric tuberculosis is on the increase, particularly in patients with AIDS (Brody et al, 1986; Dao et al, 1991). Tuberculosis **may mimic almost any gastric disorder** and cannot be recognized as such either on endoscopy or on radiologic examination. Jain et al (2000) described cytologic findings in gastric brush smears from seven adult patients from India with gastric tuberculosis, confirmed by biopsies. **Slender epithelioid cells were observed in all patients and granulomas, composed of epithelioid and Langhans' type giant cells, were observed in three patients.** Acid fast bacilli could be demonstrated in gastric smears in four of these patients but not in the biopsies. The findings are of note because gastric tuberculosis, previously a very rare disorder, has now been observed in AIDS patients (Brody et al, 1986; Das et al, 1998). For illustrations of cytologic presentation of tuberculosis, see Figures 10-22 and 19-33 (cervix and lung).

Gastric Syphilis

Ulcerative gastric lesions may occur in secondary and tertiary syphilis. Prolla et al (1970) described the cytologic findings in two such cases. Atypical cells, **presumably atypical macrophages or epithelioid cells with large nuclei and prominent nucleoli**, were observed. **Langhans' type giant cells** were also noted.

Other Granulomatous Inflammatory Lesions of the Stomach

The cytologic findings in **granulomatous disorders, regardless of etiology, are similar to those described above for tuberculosis and syphilis** and additional clinical and bacteriologic work-up may be required to determine the nature of the disorder. Thus, markedly atypical giant cells were observed by Bennington et al (1968) in a case of **gastric sarcoidosis**. Drake (1985) described **epithelioid cells and multinucleated giant cells in gastric brushings of a patient with Crohn's disease**.

Malacoplakia

Malacoplakia of the stomach has been described (summary in Flint and Murad, 1984).

Cytologic presentation of this rare disorder is discussed in Chapters 19 and 22.

Gastric Amyloidosis

Yang (1995) described a case of gastric amyloidosis observed in a gastric brush specimen. Fragments of eosinophilic material, representing amyloid, were observed in company of normal gastric cells. The diagnosis was confirmed by special stains and electron microscopy.

Ménétrier's Disease

Ménétrier's disease is a disorder of gastric epithelium in which **gastric rugae are markedly thickened** ("hypertrophic gastritis"). This disorder **may be associated with gastric polyps and carcinoma** (Appelman, 1984; Wood et al, 1983). There is no known cytologic counterpart of this condition.

Gas Cysts of the Intestine

Gas cysts of the stomach are rare, usually occurring in **disseminated intestinal gas cysts or pneumatosis cystoides intestinorum**, a bizarre disorder of unknown etiology (summary in Koss, 1952). The **cysts are often lined by flattened, multinucleated giant cells of foreign body type**. Such cells were observed in smears in association with gastric carcinoma in a case reported by Bhatal et al (1985).

Pernicious Anemia

Pernicious anemia is a chronic hematologic disorder associated with vitamin B₁₂ or folic acid deficiency and atrophic

P.873

gastritis and, therefore, is a risk factor for gastric cancer (Toh et al, 1997). The issue of specific cytologic abnormalities in pernicious anemia and other states of vitamin B₁₂ deficiencies were previously discussed in reference to the uterine cervix and the oral cavity (see Chaps. 17 and 21). Graham and Rheault (1954) and Massey and Rubin (1954) reported in patients with pernicious anemia **gastric and squamous cells with abnormally enlarged nuclei, similar to dyskaryotic (dysplastic) cells**. On the other hand, Schade (1959, 1960B) denied the existence of any specific cytologic or histologic alterations of the gastric mucosa in pernicious anemia. Intestinalization of gastric mucosa (or atrophic gastritis), described above, is, in Schade's experience, a common background of cancers developing in the presence or absence of the hematologic disorder. Personal experience indicates that slightly atypical squamous cells with enlarged nuclei occur quite often in gastric washings of patients with other cancers. A hematologic investigation of several such patients **failed to reveal a relationship between these cell changes and pernicious anemia**. It is entirely possible that the mechanical effects of intubation of the esophagus or, for that matter, a number of dietary deficiencies—such as vitamin B₁₂ or folic acid deficiency—may account for these abnormalities. Takeda (1983) illustrated three clusters of enlarged, bland, empty-looking nuclei in gastric cells in pernicious anemia. Drake (1985) also speaks of "**active**" **gastric cells, with visible nucleoli**, in pernicious anemia. The specificity or, for that matter, diagnostic value, of such changes is in doubt.

Gastric Atypias Caused by Treatment

Chemotherapy by **hepatic artery infusion** for metastatic tumors in the liver **affects gastric**

epithelium, causing a radiomimetic effect. **Cell enlargement, with preservation of the normal nucleocytoplasmic ratio, binucleation, and multinucleation of gastric epithelial cells** in gastric brushing material and biopsies, were reported in six patients with secondary gastric ulceration by Becker et al, 1986.

Chemoradiotherapy for esophageal cancer may also lead to significant abnormalities of gastric epithelium that closely **resemble naturally-occurring precancerous lesions (dysplasia)** (Brien et al, 2001). The differential diagnosis between the chemoradiotherapy-induced and naturally occurring precancerous lesions is discussed below.

BENIGN GASTRIC TUMORS

Gastric Polyps

Benign gastric polyps cannot be recognized cytologically **unless fragments of such tumors are present in the exfoliated material processed as a minibiopsy or cell block**. In this case, the interpretation is that of a biopsy specimen. Occasionally, **atypical (adenomatous) polyps may cause the same diagnostic problems as described for gastric ulcer**.

Polypoid carcinomas, on the other hand, can be readily distinguished from benign polyps because of their characteristic cytologic presentation, described below.

Benign GIST tumors are discussed below.

MALIGNANT GASTRIC TUMORS

Carcinoma of Stomach

Epidemiology

Gastric carcinoma is exceedingly common in Japan, Korea, certain other areas in Asia, South America, and Eastern Europe. Its **incidence has been declining sharply in the Western world**, even among people of Japanese ancestry living in Hawaii and the continental United States (Haenszel et al, 1976; Craanen et al, 1992; Fuchs and Mayer, 1995). A similar drop has been observed in Europe (Fuchs and Mayer, 1995). Current evidence suggests that the **frequency of tumors in the distal portion of the stomach is decreasing, whereas that of cancers of the proximal stomach (cardia) may be on the rise**, perhaps because of the increased occurrence of Barrett's esophagus, discussed earlier in this chapter (Craanen et al, 1992; Correa and Chen, 1994; Fuchs and Mayer, 1995). It is generally assumed that dietary factors are responsible, although the exact cause-effect relationship between nutrients and gastric cancer has not been established. **Pernicious anemia is a known risk factor** for gastric cancer (Toh et al, 1997). There is also evidence that *H. pylori* may play a role in the genesis of this group of tumors, although the mechanisms are still speculative (Uemura et al, 2001). It is generally assumed that, in cancer, the bacterium interacts with gastric epithelium in a different manner than in gastritis or gastric ulcer (Parsonnet et al, 1991; Forman et al, 1991; Sipponen et al, 1998; Chen et al, 1999; Ge and Taylor, 1999; Suerbaum and Mitchetti, 2002; Amieva et al, 2003).

It has also been shown that diffuse gastric cancer occurs with very **high frequency in families showing mutation of the adhesion gene E cadherin**. In young members of such families, asymptomatic early gastric cancer may be observed (Huntsman et al, 2001).

Clinical Presentation

The clinical symptoms of gastric carcinoma are not specific. In early stages, the disease is often asymptomatic whereas in advanced stages "indigestion," vomiting, hematemesis and melena and, ultimately, pain develop. Severe anemia is often observed.

On endoscopic inspection, gastric carcinomas may appear as a defect of gastric mucosa with raised edges, and thus **may mimic benign gastric ulcers. More often, the tumors are polypoid or present as flat, raised plaques.** A form of gastric cancer with **diffuse infiltration of gastric wall (leather bottle stomach or linitis plastica)** is well known.

Classification and Histology

In 1965, Lauren classified gastric carcinomas into two groups: the **intestinal type** and the **diffuse type**. Lauren documented that the behavior, hence the prognosis, of the two types of tumor were different.

- **The intestinal type of carcinoma is usually associated with intestinal metaplasia, which undergoes transformation to an intramucosal carcinoma (carcinoma in**

P.874

situ), whence generally bulky, readily visible tumors are derived. Intestinal carcinomas are usually **well-differentiated adenocarcinomas**, composed of **large, mucus-producing cells**, are usually located in the distal part of the stomach, and generally have a better prognosis than the diffuse type (Correa, 1992).

- The less common **diffuse type of gastric carcinoma (sometimes also called the *gastric type*) is derived from glandular crypts and is usually not accompanied by either intestinal metaplasia or intramucosal carcinoma. The diffuse type of gastric carcinoma is composed of small cancer cells (including the signet ring cell types) and tends to infiltrate the gastric wall early and deeply; hence, it usually appears as a flat or ulcerated lesion, with poor prognosis.** A diagram in Figure 24-20 summarizes these events. There are also cases of gastric cancer wherein both types of disease occur in the same stomach.

The confirmatory evidence of this classification scheme was provided by Japanese investigators who studied small, early gastric cancers discovered as a part of the cancer detection effort. **The genesis of the two types of cancer could be confirmed by these studies** (summary in Takeda 1983, 1984). There is other supporting evidence for this concept. In a study of distribution of H-*ras* oncogene product, protein p21, it was documented by Czerniak et al (1989) that, in the intestinal type of gastric cancer, p21 was expressed in areas of intestinal metaplasia and adjacent carcinoma in situ. In the diffuse type, p21 expression was evident in morphologically normal mucosa, apparently the source of cancer. Werner et al (2001) reviewed the molecular bases of the genesis of the two types of gastric carcinoma.

Figure 24-20 Diagrammatic representation of the events in the two types of gastric carcinoma, as suggested by Hattori and Fujita (cited by Takeda, 1984). *Top row:* Events in carcinoma of the intestinal type starting with a single cell transformation (*black cell*), the process involves gastric glands leading to an intramucosal carcinoma (carcinoma in situ), whence bulky, generally well-differentiated gastric cancers are derived. *Bottom row:* Events in carcinoma of diffuse type: the cancer cells, usually small and poorly differentiated (*black*) originate in glandular crypts and infiltrate the adjacent gastric wall without forming a carcinoma in situ. [Modified from Takeda M. Gastric cytology—recent developments. In Koss LG, Colman OV (eds). *Advances in Clinical Cytology*, Vol 2. New York, Masson, 1984, pp 49-65, with permission.]

Cytology of Advanced Gastric Carcinoma

The concept of the two types of gastric cancer is not only of theoretical, but also of practical diagnostic and prognostic value and is reflected in histology and cytology of gastric carcinoma.

Carcinomas of the intestinal type shed large, readily recognizable cancer cells, whereas carcinomas of the diffuse type are characterized by smaller, sometimes inconspicuous cancer cells. Pilotti et al (1977) successfully tested this type of classification of gastric carcinoma by gastric cytology in 78 patients. Takeda et al (1981) applied this classification to cytologic samples in 119 cases of early gastric carcinoma with excellent results. Incidentally, there are no differences in abnormal DNA ploidy values between these two tumor types (Czerniak et al, 1987B).

In **gastric lavage specimens**, the **background of smears** often contains evidence of **inflammation and necrosis** that may obscure the cytologic features. **Direct brush**

specimens, particularly if obtained from the surface of the lesion, may also contain a great deal of necrotic material. Perhaps the **easiest to interpret are lavage specimens obtained by means of a jet of fluid under direct gastroscopic control.**

In all types of gastric cancer, the presence of single cancer cells with identifiable malignant features is an important diagnostic prerequisite.

Cytology of Gastric Adenocarcinoma of Intestinal Type

The intestinal-type tumors usually shed **large cancer cells of cuboidal or columnar configuration.** The **size** of the

P.875

cancer cells may be variable, but **extreme size differences are rare.** The cancer cells are **dispersed** or form **loosely structured, tri-dimensional clusters, sometimes of papillary configuration,** which differ from tightly knit, honeycomb-type flat clusters of benign gastric cells, often observed in the same smears (Fig. 24-21). Cell clusters are more common in brush specimens than in lavage specimens. Multinucleated giant cancer cells are seen from time to time.

The fragile cytoplasm of the cancer cells may be stripped or damaged, leaving behind **characteristic enlarged, pale or translucent nuclei with a prominent nuclear membrane that is often jagged or indented. Within the nuclei, there are large, single or multiple, spherical or irregular, comma-shaped nucleoli** (Fig. 24-21B). **Nuclear hyperchromasia,** or at least **coarse granularity of the chromatin and opaque appearance of the nuclei, may be observed,** but this feature is not always dominant. Truly **hyperchromatic cancer cells** may be occasionally observed in gastric washings (Fig. 24-21C), most likely representing dead cells removed from the surface of the tumor.

The **differential diagnosis of gastric adenocarcinoma** of intestinal type is mainly with **chronic peptic ulcer** (see above) and **regenerating gastric epithelium, as observed in aspirin gastritis** and chemoradiotherapy-induced changes (Brien et al, 2001). In most instances, the abundance of the characteristic cancer cells in the cytologic specimen is sufficiently persuasive for the diagnosis of cancer to be made. If the evidence is scanty and limited to a few atypical cells, however, the clinical history and roentgenologic findings are of significant assistance in avoiding errors.

(*A:* Composite photograph obtained by PAPNET. With the permission of TriPath Imaging, Burlington, NC.)

Cytology of Gastric Adenocarcinoma of Diffuse (“Gastric”) Type

In tumors of this type, the cancer cells are small, often inconspicuous, and approximately spherical in configuration. The nuclei are relatively large, somewhat hyperchromatic, and often contain conspicuous nucleoli (Fig. 24-22A,C). The cytoplasm is scanty, basophilic, often poorly preserved. In direct brush specimens, the recognition of the malignant nature of the small cells is relatively easy (Fig. 24-22A,B). In gastric lavage specimens, the cells are sometimes difficult to identify, particularly if the material contains many contaminating squamous cells and the tumor is very poorly differentiated (Fig. 24-22C,D). In some cases, molding of

P.876

the small cells may be observed. Rarely, bi- or multinucleated cells may occur.

Figure 24-22 Diffuse gastric type carcinomas. *A*. Dispersed relatively small cancer cells with nuclear irregularities, some hyperchromasia and prominent nucleoli, corresponding to the tissue pattern shown in *B*. The tumor is composed of sheets of small cells. *C*. Scattered small cancer cells with prominent nucleoli in gastric lavage, also containing squamous cells. *D*. Corresponding tissue lesion with a very poorly differentiated small cell carcinoma.

The **differential diagnosis** of anaplastic carcinomas comprises metastatic (or swallowed) cells of **bronchogenic oat cell carcinoma** and **malignant lymphoma** (see below).

Signet ring-type cells are recognized by their usually large size and **large cytoplasmic vacuoles**, pushing the nucleus to the periphery. Because similarly structured benign cells may also occur, it is important to ascertain that the signet ring cell has the **nuclear characteristics of cancer**, namely large, **clear nuclei with irregularly shaped nuclear membrane and large, irregular nucleoli or large, hyperchromatic nuclei** (Fig. 24-23A,B).

Mixed Types of Gastric Carcinomas

Rarely, **the intestinal and diffuse type of gastric carcinoma may occur simultaneously**. Pilotti et al (1977) identified only 2 such cases in 78 patients with gastric cancer. The cytologic presentation combined the features of both tumor types.

Rare Types of Gastric Carcinoma

The rare **colloid carcinomas** may shed compact clusters of large cancer cells, with large nucleoli, containing cytoplasmic mucus that can be visualized with mucicarmine (Fig. 24-23C,D).

Squamous carcinomas or a mixture of squamous and adenocarcinoma (**adenosquamous carcinomas**) may occur in the **area of the cardia** and are similar to esophageal carcinomas of the same type (Fig. 24-24). Usually, the squamous carcinomas are poorly differentiated (epidermoid carcinomas). Keratin-forming squamous cancers are rare. In the presence of a squamous component, **swallowed cancer cells from a tumor of the respiratory tract or esophagus must be considered in the differential diagnosis**.

Rare malignant epithelial tumors combining **features of an adenocarcinoma and a carcinoid** have been recognized in cytologic material (Wheeler et al, 1984). **Large, columnar cells of an adenocarcinoma and small, monotonous cells of a carcinoid** were observed side by side in the same gastric brush smear.

Gastric carcinomas have been observed in **Ménétrier's disease** (Wood et al, 1983; also see above). An unusual association of **gas cysts of the stomach with gastric cancer** was reported by Bhatal et al (1985). **Multinucleated giant cells of foreign body type**, which are characteristic of these cysts were observed in smears **next to malignant cells**.

PRECURSOR LESIONS OF GASTRIC CARCINOMA: EARLY SUPERFICIAL CARCINOMA AND "DYSPLASIA"

Although it is clear that invasive gastric cancer has to be preceded by a precancerous abnormality of gastric epithelium, the documentation of this sequence of events is relatively recent. The pioneering work in the **recognition of gastric carcinoma in situ and related abnormalities** was performed by Dr. R. O. K. Schade, during his tenure at Newcastle-on-Tyne, UK (Schade 1956A,B, 1959, 1960A,B, 1963). He studied patients who either had vague clinical complaints referable to the gastrointestinal tract or had pernicious anemia and, therefore, were at risk for the

P.878

development of gastric cancer. The **cytologic specimens** were obtained by washing the stomach with saline through a simple gastric tube on 3 consecutive days and examining smears obtained from the centrifuged sediment. Within 5 years (1954-1959), Schade was able to

diagnose by cytology 41 cases of **very superficially invasive or preinvasive cancer of the stomach, of which 16 were in entirely asymptomatic patients.**

The work of Schade found a following primarily in Japan, where gastric carcinoma is a national scourge, with the hope that early detection of gastric cancer can modify the dismal mortality statistics. There, the **gastric lavage was supplemented by fiberoptic gastroscopy which was initially developed by the Japanese bioindustry specifically for the purpose of gastric cancer detection.** The Japanese health services provided mobile health stations as fully equipped and staffed buses in order to make gastric cancer detection available to all citizens, even those living in small, remote villages. Incidentally, the role of the mobile health stations was subsequently extended to offer cervicovaginal smears and chest x-rays, thus including cervix and lung cancers in the cancer prevention scheme.

The accomplishments of the Japanese scientists have radically altered the outlook on the diagnosis and prognosis of gastric carcinoma (for summaries see Inokuchi, 1966; Kasugai, 1968; Kasugai and Kobayashi, 1974). A large number of papers have documented that the survival of patients treated for superficial carcinoma is vastly superior to survival of treated patients with more advanced gastric cancer. As early as 1966, Inokuchi et al reported a 5-year cure rate of over 90%. Yamazaki et al (1989) reported 5-year survival of 509 treated patients with **early gastric cancer** as close to 100%. By contrast, about one-half of 18 patients with this disorder, who were not treated for various reasons, died of gastric cancer within 5 years. The comparative survival of 350 patients with **occult, but advanced gastric cancer**, treated by curative surgical resection, was 72% after 5 years and 65% after 10 years. On the other hand, all 127 patients with advanced cancer who, for various reasons, were not treated for cure, died within 3 years.

As a consequence of these efforts, the **discovery of gastric cancer in the asymptomatic early stage, notably as superficial carcinoma or carcinoma in situ, has become the rule, rather than the exception in Japan.** The techniques of gastric cancer diagnosis have now achieved worldwide dissemination, particularly fiberoptic gastroscopy combined with gastric cytology and biopsies.

In spite of this progress, the **older, well-tolerated and inexpensive technique of gastric**

lavage still has its place, particularly in the developing countries, as a means of gastric cancer detection and diagnosis in high-risk patients, for example, in patients with pernicious anemia or those with minimal symptoms referable to the upper gastrointestinal tract.

Endoscopic Presentation and Histology

The extensive Japanese experience in the detection of early gastric cancer has led to the formulation of new concepts of this disease. Although the Japanese investigators recognized that **carcinoma confined to the gastric epithelium (true carcinoma in situ) does exist**, it was also noted that **even a very superficial invasion of the submucosa may occasionally be associated with metastases to the regional lymph nodes**. Hence, it is considered prudent to replace the term *carcinoma in situ* with ***superficial or surface gastric carcinoma***.

The **endoscopic appearance** of early (superficial) gastric carcinoma could be separated into three principal types (Fig. 24-25).

- **Type I is a polypoid lesion**, elevated above the normal level of the epithelium, **usually a carcinoma of intestinal type**.
- **Type II is a flat lesion**, either slightly elevated above the level of the epithelium or slightly depressed, **usually a carcinoma of intestinal type**.
- **Type III is a superficially ulcerated lesion**, usually a **carcinoma of diffuse (gastric) type that may be invasive at the time of discovery**.

Type I, II abnormalities are by far more common than type III. A combination of the three types is sometimes observed. It is still not clear how much time is required for the progression of untreated superficial carcinoma of gastric mucosa to fully invasive carcinoma. The progression is likely to be much slower in the intestinal than in the diffuse type of lesions. The evidence at hand strongly suggests, however, that superficial gastric cancers, particularly of the diffuse type, are potentially highly dangerous and must be treated.

Superficial Carcinoma

The histologic appearance of the early lesions is illustrated in Figure 24-25. The early stages of **intestinal type of gastric carcinoma** are characterized by **disorderly glands of variable sizes, lined by cells with hyperchromatic nuclei, often with prominent nucleoli**. The **diffuse type of lesions** is characterized by an **accumulation of small, often signet-ring type of cancer cells within the epithelium**, infiltrating and often replacing the normal glands.

“Dysplasia” of Gastric Epithelium

Regardless of the diagnostic sophistication of the observer, gastric histology (and cytology) occasionally poses major diagnostic dilemmas. In incidental endoscopic biopsies, there occur epithelial abnormalities that are clearly on the border of cancerous changes in the form of **atrophic gastritis with good preservation of the glandular pattern, but significant nuclear abnormalities within the glands**. Similar lesions were classified as **“dysplasia”** of gastric epithelium (Morson et al, 1980; Jass, 1983). The parallel may be drawn with “dysplasia” occurring in Barrett's esophagus although, to my knowledge, the follow-up of such gastric lesions is limited. Rotterdam et al (1993) cite several follow-up studies that strongly suggest that “severe dysplasia” is a precursor of gastric cancer. The exact clinical significance of such

changes is not fully

P.879

understood, and the therapeutic dilemma is often resolved by surgical intervention that is dictated by prudence, rather than by biologic facts. The **difficulties in the differential diagnosis of gastric “dysplasia” with epithelial abnormalities occurring in chronic gastric ulcers and “aspirin” gastritis have been discussed above and must be considered in the differential diagnosis of such lesions.** The differential diagnosis must also include **gastric epithelial abnormalities** observed in patients undergoing **chemoradiotherapy for esophageal cancer** (see below).

Figure 24-25 Superficial gastric carcinomas. *A,B.* Type I, polypoid lesion; well-differentiated intestinal type of adenocarcinoma. *C,D.* Type II, flat lesion; moderately well-differentiated adenocarcinoma of intestinal type. *E,F.* Type III, ulcerated lesion; signet-ring carcinoma of diffuse type. (Cases courtesy of Prof. S. Shida, Dokkyo University, Mibu, Japan.)

Cytology

Superficial Carcinoma (Carcinoma In Situ), Intestinal Type

In gastric lavage smears from cases of gastric carcinoma in situ (superficial carcinoma) reported by Schade (1963),

P.880

abundant cancer cells were present (Fig. 24-26). There was no evidence of necrosis that so often complicates the problem of cytologic diagnosis of advanced and ulcerated gastric cancers. The lesions observed by Schade were mainly of the **intestinal type**. The **cancer cells were large, cuboidal, and contained large, somewhat hyperchromatic nuclei of variable sizes, with prominent multiple nucleoli**. The cytologic findings reflected the tissue abnormality wherein cancer cells lined gastric glands of irregular shape and variable sizes. In superficial carcinoma, cancer cells tend to form more **compact clusters** than in more advanced cancers. The nuclear and nucleolar abnormalities, particularly the latter, become of paramount diagnostic significance.

Figure 24-26 Cluster of cancer cells (*A*) and tissue section (*B*) from a case asymptomatic carcinoma in situ of the stomach diagnosed by gastric washings. (Courtesy of Dr. R. O. K. Shade, Newcastle-upon-Tyne, England.)

Schade's observations that **cytologic preparations from superficial carcinomas are easier to interpret than material from advanced gastric cancers** have received ample confirmation from Japanese sources and are also in keeping with personal experience. The specimens are usually free of extensive necrosis and debris and the cancer cells are well preserved (Fig. 24-27).

P.881

Superficial gastric carcinoma of intestinal type. *A.* Highpower view of cohesive cluster of large cancer cells with prominent nucleoli. *B.* Dispersed cancer cells with similar characteristics. *C.* Another cohesive cluster of columnar gastric cells with markedly atypical nuclei. *D.* Tissue lesion showing gastric carcinoma in situ. (Case courtesy of Professor S. Shida, Dokkyo University, Mibu, Japan.)

Superficial Carcinoma, Diffuse Type

The **rare superficial diffuse carcinomas of signet ring type** also shed better preserved cancer cells in which the presence of mucus-containing vacuoles and the morphologic abnormalities of the eccentric nucleus are evident. An example of such cells is shown in Figure 24-23A.

“Dysplasia” of Gastric Epithelium

Our experience with cytology of gastric dysplasia is limited. The lesion may pose major diagnostic dilemmas in the **correlation of cytologic and histologic findings**, as shown in the example illustrated in Figure 24-28. The 54-year-old man had vague abdominal complaints, but no radiographic lesion of note. Cytologic examination of a gastric wash specimen revealed

numerous **clusters of highly abnormal large cells with hyperchromatic nuclei and abnormal chromatin patterns** that were diagnosed as gastric carcinoma. The histologic examination of the resected sleeve of the stomach revealed an atrophic gastritis with good preservation of the glandular pattern but significant nuclear abnormalities within the glands. The difficulties of **differential diagnosis between gastric dysplasia and cytologic abnormalities in chronic gastric ulcers and aspirin gastritis** have been discussed above. A careful review of history and knowledge of endoscopic findings is necessary before the diagnosis of gastric "dysplasia" is established. Another potential source of error is the "dysplasia-like" changes in gastric epithelium caused by **chemoradiotherapy for esophageal cancer** (Brien et al, 2001). These authors suggested that two immunochemical tests, performed on gastric biopsies, may assist in the differential diagnosis between benign gastric epithelial abnormalities and true dysplasia. With the use of **antibody MiB-1**, the proliferation of noncancerous gastric epithelium was **limited** to the depth of gastric glandular crypts whereas, in true dysplasia, the reaction was generalized and involved surface epithelium. Nuclear staining with **antibody to p53** was generally negative in benign lesions and strongly positive in dysplasia.

CYTOLOGY IN THE DIAGNOSIS OF RECURRENT GASTRIC CARCINOMA

After partial gastrectomy for gastric cancer, it may occasionally be possible to diagnose recurring tumor by means of gastric washings. The matter is more often than not of theoretic value only, since in most such cases metastases are present. Offerhaus et al (1984) observed that "**dysplasia**" of the **residual gastric stump** after resection for gastric carcinoma was a precursor lesion of recurrent gastric cancer. Unfortunately, the study did not include a cytologic component.

P.882

Biopsy of gastric epithelium showing moderate atypia of the lining of the glands, interpreted as a precancerous lesion.

RESULTS OF CYTOLOGIC DIAGNOSIS OF GASTRIC CARCINOMA

It may be of some interest that even before the introduction of fiberoptic instruments, specialized laboratories, often directed by gastroenterologists, reported a very high rate of accuracy for gastric cancers diagnosed by cytology **in lavage specimens**. Errors in the diagnosis of gastric cancer in the published series varied from 0% to 4.3%. The results of early personal work in gastric cytology were summarized by McNeer (1967).

Since the introduction of fiberoptic instruments in the 1960s, significant progress has been mainly in the **discovery of early gastric carcinomas** that offer significantly better therapeutic options than more advanced gastric cancer. A dramatic illustration of the change that occurred with the introduction of fiberoptic instruments was provided by Kasugai and Kobayashi (1974), comparing the results of the lavage method and cell samples obtained under direct vision (Table 24-3). In competent hands, combining brush cytology with multiple gastric biopsies, the **diagnosis of early gastric cancer** may be achieved in nearly 100% of such lesions.

Still, there is some controversy in reference to the value of brush cytology when compared with direct biopsy of gastric lesion. Thus, Cook et al (1988) suggested that the brushings add very little to biopsies and are a source of “false-positive” errors. In the hands of Qizilbash et al (1980), the brush specimens were positive in about 89% of the cases of gastric cancer, the biopsy in 93%, and the combination of the two methods in over 95% of the cases. A more optimistic evaluation was offered by Gupta and Rogers (1983), who diagnosed, by brush cytology 21 carcinomas that initially could not be documented by other means. However, these authors also recorded nine unproved, presumably false-positive diagnoses. Hughes et al (1998) studied, by logistic linear regression analysis, the results of gastric brush cytology from 100 patients from several institutions, 50 with documented benign lesions and 50 with gastric cancer. The conclusions of this study, listing the presence of **intact cancer cells, eccentric position of nuclei** and **atypical nuclei** as the three most important features of gastric cancer added little to existing knowledge. Unfortunately, the gastric cancer cases were not subclassified into the intestinal and diffuse types.

In reviewing the accumulated data, it appears that **the most important aspect of gastric cytology is the falsepositive rate, the principal sources of error being regenerating gastric epithelium, as in chronic peptic ulcer or aspirin gastritis** (see above). The accuracy of diagnoses obviously depends on quality of the specimens, their technical handling, and the competence and experience of the observer.

P.883

TABLE 24-3 COMPARISON OF CYTOLOGIC RESULTS IN THE DIAGNOSIS OF GASTRIC CANCER			
	Number of Cases of Gastric Carcinoma	Cytology Positive	Diagnostic Accuracy
Routine lavage	136	110	80.9%
Direct vision lavage			

Early carcinoma	128	122	95.3%
Advanced carcinoma	384	372	96.9%
Direct vision brushing	21	20	95.5%

(Modified from Kasugai T, Kobayashi S. Evaluation of biopsy and cytology in the diagnosis of gastric cancer. Am J Gastroenterol 62:199-203, 1974.)

GASTRIC LYMPHOMAS

Gastric lymphomas account for about 5% of gastric malignant tumors and about one half of malignant lymphomas occurring in the gastro-intestinal tract. Although the general classification of malignant lymphomas is discussed in Chapter 31, gastric lymphomas have specific features that warrant a separate discussion. Of particular interest are the so-called **MALT** lymphomas or malignant lymphomas occurring in the **mucosa-associated lymphoid tissue**, discussed below. The clinical presentation of primary gastric malignant lymphomas is often indolent, mimicking gastric ulcer or gastritis. The tumors have a high curability rate, particularly if diagnosed early (Case Record 13-1995, Massachusetts General Hospital). Therefore, an accurate diagnosis of gastric lymphoma is of great benefit to the patient and cytologic examination of gastric brush specimens may contribute to it. It should be noted, however, that malignant lymphomas develop **beneath** the gastric epithelium, which must be invaded by tumor or ulcerated for the malignant cells to reach the gastric lumen and thus be accessible to cytologic diagnosis.

Large Cell Lymphomas

Nearly all gastric lymphomas are of non-Hodgkin's B cell type. **Large-cell malignant lymphoma of various subtypes is the most frequent form of gastric lymphoma** (Weingrad et al, 1982). The disease is intramural, but may be diagnosed cytologically if the mucosa is involved or if there is an ulcerative lesion. Because of the presence of necrotic material and debris, particularly in the presence of an ulcerated lesion, the diagnosis of lymphoma is difficult in gastric lavage. **Brush specimens**, however, usually show a **nearly pure population of malignant cells** with little debris. In the example shown in Figure 24-29A,B, **medium-sized malignant cells with very scanty cytoplasm were observed in gastric brushings**. The cells formed **loosely structured clusters** and occurred **singly**, a characteristic feature of malignant lymphomas, also emphasized by Lozowski and Hajdu (1984). The **size of the nuclei** was estimated by Lozowski and Hajdu to be twice or three times the size of normal lymphocytes. **Large, prominent, often multiple, nucleoli were noted within the granular nuclei**. Other cytologic features of large-cell gastric malignant lymphoma are similar to those seen in effusions (see Chap. 26). Thus, **nuclear protrusions, nuclear cleavage, and apoptosis (karyorrhexis) may be observed**. **Large-cell lymphoma** must be differentiated from **small-cell anaplastic carcinoma**. In the latter, **tight cell clusters and cell molding** are evident, features that are **not seen in malignant lymphomas**.

Small-Cell Malignant Lymphomas and MALT Lymphomas

Within recent years, the entity of small cell lymphoma of the stomach has been enriched by the recognition of malignant lymphomas occurring in the **mucosa-associated lymphoid tissue (MALT lymphomas)** (Isaacson and Wright, 1984; Isaacson, 1995). These tumors have several unusual features, including an indolent course, an association with *H. pylori*, and a high cure rate. It is speculated that the infection with *H. pylori* leads to a chronic inflammation with accumulation of lymphoid tissue in the gastric wall that becomes transformed into lymphoma (Zucca et al, 1998). **Most, if not all, gastric lesions, previously classified as pseudolymphomas, belong to the category of MALT lymphomas** (Sweeney et al, 1992). Occasionally, MALT lymphomas may progress to a large cell lymphoma (Chan et al, 1990).

The **cytologic diagnosis of small-cell, well-differentiated lymphocytic lymphoma is exceedingly difficult** in suboptimal material obtained by gastric lavage. The principal problem is the presence of lymphocytes in chronic gastritis or gastric ulcer. Also, the cellular and nuclear characteristics of the very small malignant lymphocytes may be insufficient to establish this diagnosis in lavage specimens.

In gastric brush specimens, the characteristic features of small cell lymphomas may be better evident. Immunocytologic stains should be of value in this diagnosis (see Chap. 31). As an example and through the courtesy of Dr. Misao Takeda (formerly of Jefferson Medical College

P.884

in Philadelphia), we had the opportunity to study the gastric smears in a case originally classified as a "pseudolymphoma" but in retrospect is an excellent example of MALT lymphoma (Fig. 24-29C,D). The smears were characterized by **very loosely structured sheets of somewhat enlarged lymphocytic cells, many containing visible nucleoli**. In retrospect, the smaller tumor cells were very similar to cells of a large cell lymphoma (compare Fig. 24-30A with Fig. 24-30C). Scattered plasma cells were also evident. The diagnosis of a malignant lymphoma could be established with confidence in this case.

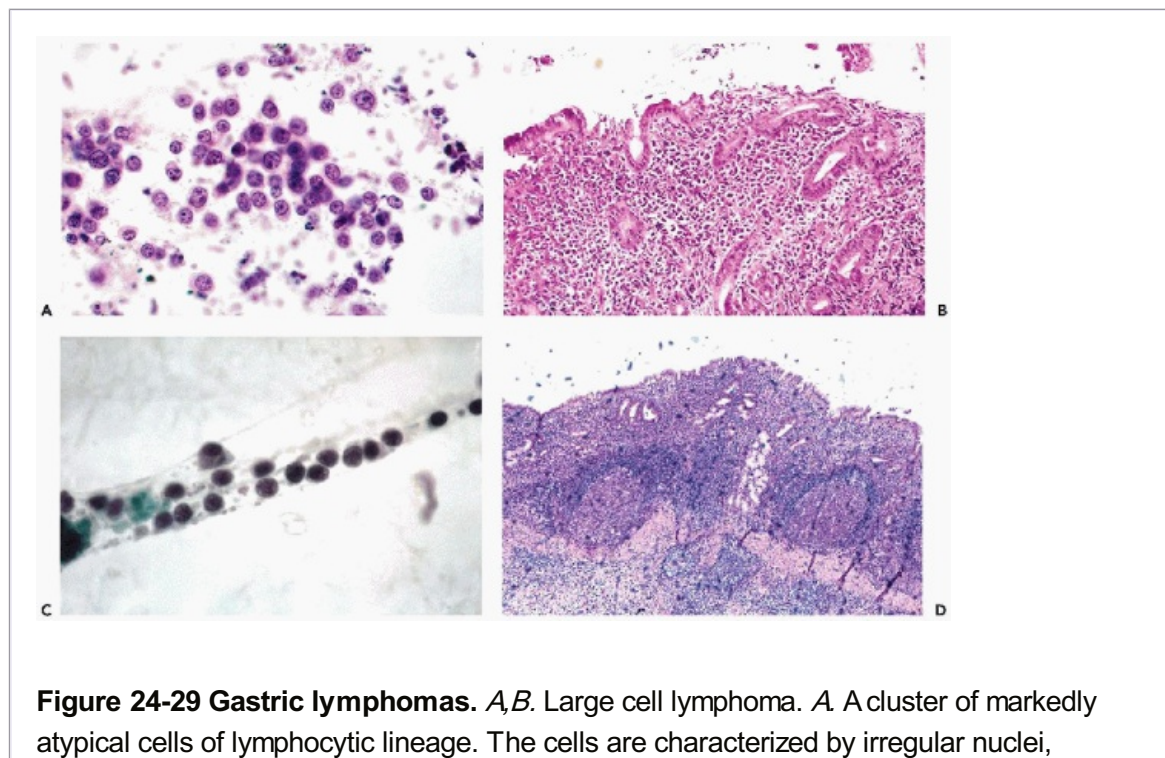

Figure 24-29 Gastric lymphomas. A,B. Large cell lymphoma. A. A cluster of markedly atypical cells of lymphocytic lineage. The cells are characterized by irregular nuclei,

prominent nucleoli and very scanty cytoplasm. *B*. The corresponding large cell lymphoma infiltrating gastric wall. *C,D*. Gastric brushing and biopsy in a lesion initially classified as *pseudolymphoma* and now reclassified as *MALT lymphoma*. The smaller cells in the gastric brush are morphologically similar to those shown in a large cell lymphoma in *A*. *D*. The gastric lesion corresponding to *C* with formation of lymphoid follicles. (*C*, higher magnifications). (*C,D* courtesy of Dr. Misao Takeda, Philadelphia.)

In the presence of lymphoma, gastric epithelial cells may disclose considerable atypia, similar to that seen in peptic ulcers and probably caused by nonspecific ulcerative or inflammatory changes in the mucosa.

Hodgkin's Disease

Primary gastric Hodgkin's disease is exceedingly rare. However, Hodgkin's disease of adjacent lymph nodes **may sometimes involve the gastric wall**. In such uncommon cases, cancer cells may be observed in exfoliated material but the specific diagnosis cannot be made in the absence of clinical data. The few clearly malignant and polyhedral cells with hyperchromatic and occasionally double nuclei mimic an epithelial tumor. Raskin et al (1958) and Rubin (1974) reported seeing Reed-Sternberg cells in gastric cytologic material but this has not been our experience.

Performance of Cytology in the Diagnosis of Gastric Lymphoma

As gastric cytology came into widespread use, the early experience with the cytologic diagnosis of malignant lymphomas was variable. Katz et al (1973) reported a relatively poor experience with cytologic diagnosis of these lesions. On the other hand, Kline and Goldstein (1973) reported successful cytologic identification in 9 of 10 patients with this group of diseases. Prolla et al (1970) identified 30 such lesions in 46 patients. Lozowski and Hajdu (1984) studied 29 cases of malignant lymphomas of the gastrointestinal tract, including 24 primary gastric lymphomas. These authors could establish a definite cytologic diagnosis in 5 of 24 gastric lymphomas, 1 of 2 lymphomas of small bowel, and all 3 colonic lymphomas. Sherman et al (1994) studied 27 patients and could establish the cytologic diagnosis in 10 of

P.885

18 patients with primary large cell type gastric malignant lymphomas and in 2 of 7 patients with metastatic lymphomas. In 2 of 4 cases with negative biopsies, cytology was suspicious. Suspicious diagnoses were also rendered in two cases of gastritis. **Thus, the role of cytology in the diagnosis of gastric malignant lymphoma is that of an ancillary technique that may occasionally contribute to the diagnosis in cases of biopsy failure or timid interpretation of histologic evidence.**

GASTROINTESTINAL STROMAL TUMORS

A variety of relatively uncommon mesenchymal tumors of gastric and intestinal walls, **previously classified as leiomyomas, leiomyosarcomas, leiomyoblastomas, neurilemmomas, gastrointestinal autonomic nerve tumor (GANT), tumors of vascular origin, etc.** are now classified **as gastrointestinal stromal tumors (GISTs)** (Hurlimann and Gardiol, 1991; Franquemont and Frierson, 1992). These tumors have in common certain clinical, molecular, and immunocytochemical features that set them apart from morphologically similar tumors of other organs. These tumors, which may occur in families, are thought to be

derived from the interstitial intestinal cells first described many years ago by Ramón y Cajal that have a growth factor receptor named **c-kit** that can be demonstrated by immunostaining with the **antibody CD117** and, in a somewhat less specific fashion, with the **antibody CD34** (Sarlomo-Rikala et al, 1998; Miettinen et al, 1999). Positive staining with the antibody CD117 has now been declared essential for the diagnosis of GIST (Fletcher et al, 2002). A family with a germline mutation of c-kit was described by Maeyama et al (2001).

Figure 24-30 Benign gastrointestinal stromal tumor (GIST) in aspirated material. *A.* A sheet of spindly cells forming a whorl. *B.* A sheet of cells, shown in *C* under higher magnification. The cells are spindly in configuration and have virtually no nuclear abnormalities. *D.* Gastric tumor corresponding to *B* and *C*, immunostaining positively for CD34. (Courtesy of Dr. Jacek Sygut, Kielce, Poland.)

About 60% of GISTs are of **spindle cell type**, corresponding to the make-up of smooth muscle or nerve tumors. About 30% of these tumors are composed of large, epithelium-like cells, corresponding to epithelioid leiomyosarcomas, previously also known as leiomyoblastomas. Suster et al (1996) described three patients with **signet ring** type cells. Most of these tumors are **benign** but about one quarter are **malignant** and capable of metastases (Miettinen et al, 1999; Trupiano et al, 2002). Tumor size greater than 5 cm in diameter is an important criterion in poor prognosis (Fletcher et al, 2000). **Stomach** is the most common site of origin of these tumors, followed by **small intestine**. These tumors are **rare** in the **large intestine**. Some of the malignant GISTs appear to respond to a drug known as **imatinib mesylate** (Gleevec, Novartis Pharmaceuticals Corporation, East Hanover, NJ) that is effective in the treatment of chronic myelogenous leukemia (summary in Joensuu et al, 2001; Savage and Antman, 2002;

P.886

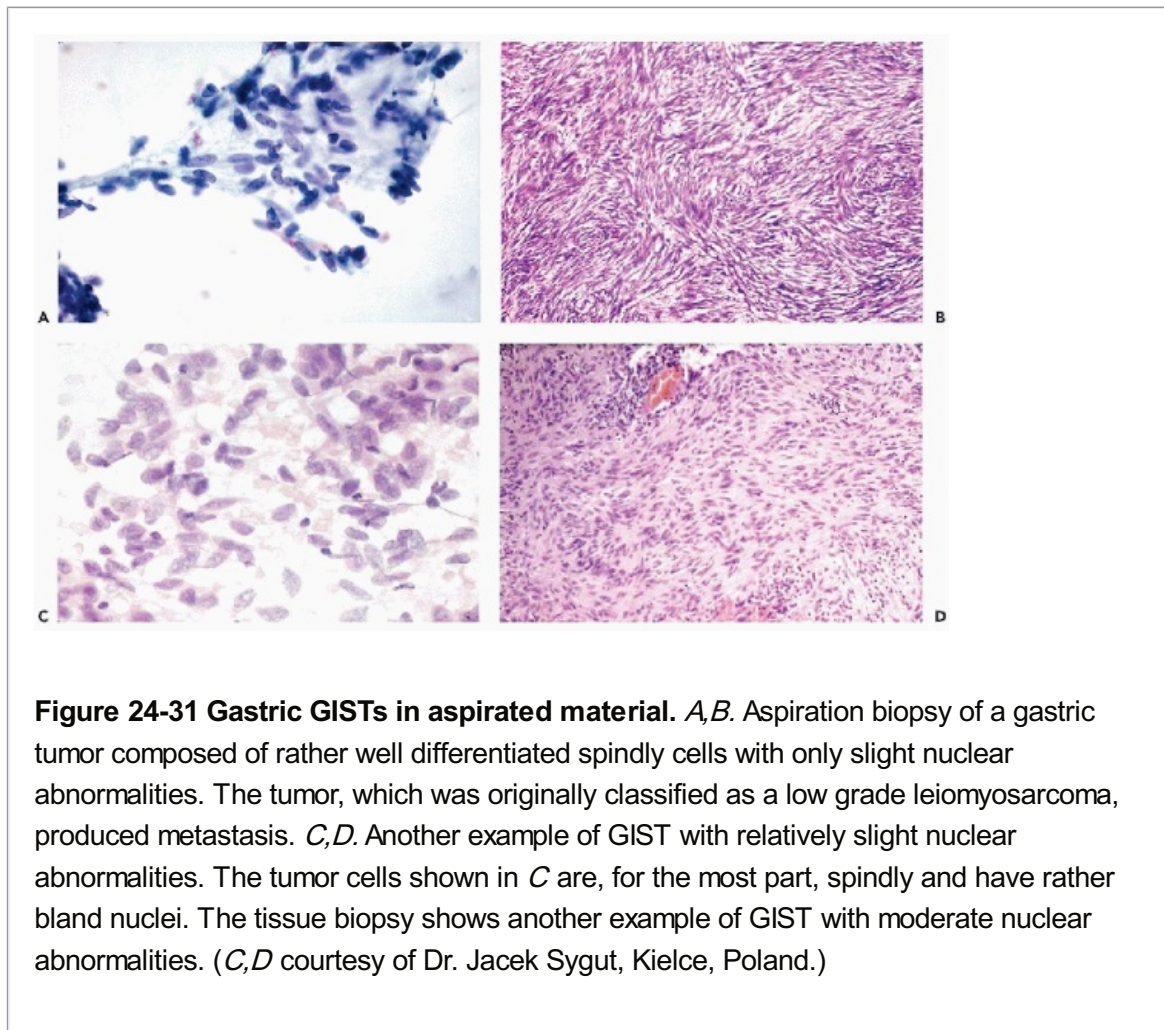

Demetri et al, 2002). It must be noted that GISTs, like lymphosarcomas, develop in the gastric wall beneath the gastric epithelium, which must become ulcerated before tumor cells can reach the gastric lumen. In such cases, the **tumor cells may be identified in gastric lavage or brushings**. However, small, nonulcerated tumors may now be aspirated under **endoscopic ultrasound guidance**, a technique described in detail below in reference to bile ducts (Stelow

et al, 2003).

Cytology

Benign GISTs

Benign GISTs correspond to leiomyomas or nerve-derived tumors composed of bundles of spindly cells with few, if any, nuclear abnormalities and low mitotic count (<5 per 50 high power fields). **These tumors can be recognized only in aspiration biopsies.** In a limited number of cases seen by us, the tumor cells in aspirates formed **distinct, loosely structured fragments, sheets or bundles of spindly cells with monotonous elongated nuclei** (Fig. 24-30). A loosely structured matrix was enveloping the cells. Single cells were very rare. The smears had a clean background and were remarkably free of debris or inflammatory cells. Tissue biopsies in such cases were negative for S-100, desmin and myoglobin antibodies but positive for CD117 and CD34. Similar findings have been reported by others (King et al, 1996; Isimbaldi et al, 1998; Li et al, 2001). The differential diagnosis includes an exceedingly rare **solitary fibrous tumor of the gastric serosa** which has a similar cytologic presentation in aspiration biopsy (Shidham et al, 1998).

Malignant GISTs

Before the concept of GIST was formulated, most of these tumors were classified as **leiomyosarcomas**, composed of bundles of **elongated, malignant spindly smooth muscle cells**. Thus, Cabré-Fiol et al (1975) observed three cases of leiomyosarcoma in gastric brush

specimens. They reported the presence of characteristic **elongated, spindle-shaped, malignant cells with large, abnormal nuclei** and large nucleoli. Similar cases were described by Qizilbash et al (1980) and by Drake (1985). Prolla and Kirsner (1972) observed elongated malignant cells in bundles *after* gastric biopsies of leiomyosarcomas. In our experience, some **GIST tumors previously classified as leiomyosarcomas may be composed of spindly cells without significant nuclear abnormalities and yet be fully capable of metastases** (Fig. 24-31A,B), an observation confirmed by Li et al (2001). In yet

P.887

another case, the spindly cells showed only slight nuclear abnormalities (Fig. 24-31C,D). Thus, the **mere presence of spindly cells in gastric specimens** should be noted as a **warning sign** that a malignant tumor may be present in the gastric wall.

The **epithelioid variant of leiomyosarcomas (leiomyoblastoma) is composed of polygonal cells that mimic an epithelial tumor**. In our experience with aspiration cytology of malignant GIST tumors of this type, the smears were composed of epithelioid-type cells with **clearly malignant nuclear features**. The malignant cells were arranged in **loosely structured tissue fragments** (Fig. 24-32A,B). Park et al (1997) reported a case of metastatic **epithelioid leiomyosarcoma** to the liver and emphasized the polygonal configuration and abundant cytoplasm of cancer cells. We also observed a case of malignant GIST tumor wherein the cells formed gland-like structures mimicking an adenocarcinoma (Fig. 24-32C,D). It is evident that only the well differentiated GISTs can be recognized as such in aspiration smears. Tumors composed of clearly malignant cells require clinical data for further classification.

Li et al (2001) described cytologic findings in aspirates of 19 GIST tumors from several institutions. These authors also stressed the tremendous variability of the cytologic presentation of these neoplasms and the absence of features predictive of their metastatic behavior.

Figure 24-32 High-grade GIST tumors of stomach. A. Aspiration smear of a tumor shown in B. The smear shows clearly malignant cells with nuclear abnormalities. The tissue biopsy in B shows a lesion classified initially as an epithelioid leiomyosarcoma. C,D. Another example of high-grade GIST tumor. In C, The cancer cells show a

pseudoglandular arrangement mimicking a gastric carcinoma. *D.* The tissue lesion in the same case, initially diagnosed as leiomyosarcoma.

OTHER RARE MALIGNANT TUMORS INVOLVING THE STOMACH

A case of **primary gastric melanoma**, with a contributory diagnosis by cytology, was reported by Reed et al (1962). Pigmented malignant cells were observed.

Gorczyca and Woyke (1992) reported a case of **primary gastric choriocarcinoma**, diagnosed in a brush specimen. Bizarre tumor cells, some forming syncytial clusters, were observed. The tumor cells stained for **cytokeratins and human chorionic gonadotropin**. These authors emphasized, however, that **these immunostains may also be positive in pure gastric carcinomas** and, therefore, the morphologic appearance of the tumor cells was of diagnostic importance. **Carcinoids** and other endocrine gastric tumors are discussed below in the colon section.

Metastatic tumors to the stomach may occasionally be diagnosed by gastric washings. Such was the case in a few instances of **mammary carcinoma** observed by us. It should be noted that **patients with mammary carcinoma treated**

P.888

with steroids are prone to gastric metastases. Somewhat more frequently, **swallowed cancer cells of esophageal, laryngeal, and pulmonary origin may be observed in gastric specimens**. This is an **important potential source of diagnostic error** that may result in an unnecessary laparotomy or even gastric resection.

THE COLON AND THE RECTUM

Carcinoma of colon and rectum is the second most lethal cancer in the United States. Because the results of treatment of advanced colonic cancer are unsatisfactory with mortality rate depending on stage of the disease, a major effort is afoot to prevent the disease by recognizing and removing precancerous lesions, or at least to diagnose the disease in early stages.

There are three main approaches to screening for colon cancer: double contrast barium enema, colonoscopy, and detection of occult blood in the stool (summaries in Lieberman, 1998; Winawer, 1999; Bond, 1999).

- **Double contrast barium enema.** This radiologic technique allows the visualization of small space-occupying lesions of the colon. There is considerable debate whether the technique, which is time-consuming and not comfortable for patients, but less expensive than colonoscopy, can assume the role of an effective tool of early cancer detection (Dodd, 1992).
- **Colonoscopy.** Colonoscopy, or inspection of the entire large bowel by fiberoptic instruments, is an expensive and time-consuming technique, requiring the services of a skilled gastroenterologist. There is reasonable consensus that this is, by far, the most effective colon cancer prevention technique, with a relatively small margin of error in the recognition of precursor lesions (reviews in Shinya, 1982; Rex et al, 1997; Inger, 1999).
- **Detection of occult blood in stools.** This is by far the least expensive technique of colon cancer detection that is applicable on a large scale. Slide-like commercial devices are used to detect blood in tiny samples of stool. The slides can be used by the patients in the privacy

of their homes or in the physicians' offices. The presence of blood is indicated by a change in color of the slide. Unfortunately, the test is of low specificity, and the presence of blood in stool must be further clarified by additional procedures (Gnauck, 1977). In mass surveys, the test has been shown to be useful in identifying patients at risk (Mandel et al, 1993; Thomas et al, 1995; Scotiniotis et al, 1999).

CYTOLOGIC TECHNIQUES IN THE DIAGNOSIS OF CARCINOMA OF COLON AND ITS PRECURSOR LESIONS

Cytologic techniques have not entered into the mainstream of clinical approaches to colon cancer prevention or diagnosis. Still, there is strong evidence that in skilled hands cytology may be helpful in the diagnosis of colon cancer and its precursor lesions.

Historical Overview

Before the onset of the era of sophisticated radiologic approaches and colonoscopy, the colon has been the target of cytologic investigations for detection or early diagnosis of colonic cancer. Bader and Papanicolaou (1952) used a **rectal-washing apparatus** devised by Loeb (Loeb and Scapier, 1951) to obtain samples from the rectum and lower sigmoid for the diagnosis of cancer located in the descending colon.

The concept of **colonic lavage** for the diagnosis of occult colonic carcinomas was subsequently advocated by Raskin and Pleticka (1964, 1971), who achieved remarkable diagnostic results in selected symptomatic patients without radiologic abnormalities on barium enema.*

Several other lavage techniques were advocated (DeLuca et al, 1974; Katz et al, 1974, 1977). In ulcerative colitis, Katz et al (1977) advocated **segmental lavage of areas of colon** showing strictures, grossly distorted mucosa, or endoscopically inaccessible areas.†

Casts of colon obtained by injecting a soft plastic (Spjut et al, 1963), and even **sponges packed in soluble capsules** (Cromarty, 1977), were used to secure cellular samples from the colon.

Isotonic colon lavage solutions, taken by mouth and used for bowel cleansing before colonoscopy, may also serve as a cell-collecting fluid with satisfactory diagnostic results (Rozen et al, 1990; Rosman et al, 1994). A similar experiment was conducted on 12 patients before colonoscopy by Greenebaum and Brandt (1998; unpublished data) at Montefiore Medical Center but failed to be of value.

For **rectal cancer within the reach of the examiner's finger**, Linehan et al (1983) advocated the preparation of a **smear from the surface of the glove**. The method was successful in the diagnosis of several adenocarcinomas and squamous cancers, as confirmed by Soni and Dhamne (1991) and by Wilson et al (1993).

Current Status

With the widespread use of colonoscopy, **direct brushing techniques** have become the preferred method of collection of cytology specimens. Colorectal cytology is primarily useful in the **identification of cancer or precancerous states**

P.889

in high-risk patients (patients with familial polyposis of colon, ulcerative colitis, or

patients previously treated for colon cancer) and for the clarification of obscure radiographic or colonoscopic findings. Several observers reported that brushing cytology of colon increases the yield of precancerous lesions and early carcinoma when compared with biopsies (Winawer et al, 1978; Melville et al, 1988; Ehya and O'Hara, 1990).

NORMAL COLON

Histology

The mucosa of the large bowel is composed of a **single or a double layer of columnar cells, arranged in simple tubular glands** (see Fig. 5-6). There are **numerous mucus-producing goblet cells** within the mucosa. The intervening columnar cells have an opaque cytoplasm. Electron microscopic studies have shown that the surface-lining cells are columnar with striated border; **on the surface, there are numerous microvilli with electro-opaque rootlets**, a feature that **may assist in the recognition of colonic cancer cells in metastases** (see Chap. 26). The cytoplasm of the mucus-producing goblet cells is filled with mucus-containing vacuoles that are discharged after reaching the surface of the cell.

Cytology

One of the most difficult tasks in obtaining cytologic specimens from this area is to limit the amount of debris to ensure a clean smear. The **cytologic features of rectal and sigmoid washings or brushings** in the absence of disease are rarely obtained but are simple to interpret. **The epithelial cells are easily recognized as slender columnar cells with pale spherical nuclei located in the approximate center of the cells. They are similar to normal gastric cells** (see Fig. 24-16B). **Depending on the method of securing the specimen, these cells occur singly and in loosely structured clusters** (in colonic washings) or as **tightly knit clusters or bundles of parallel cells** (in brush specimens). **Also present are mucus-producing, goblet cells** (described in detail in Chap. 19), macrophages, leukocytes, some **squamous cells of anal origin** and, almost invariably, some debris.

Figure 24-33 A. Acute nonspecific colitis in brush smear. The smear is composed mainly of inflammatory cells and some necrotic epithelium. B. Amebiasis. The spherical organisms (arrow) may be seen in the midst of the inflammatory exudate.

ACUTE INFLAMMATORY DISEASES

Acute Colitis

Disorders such as **amebic colitis** or **acute diverticulitis** result in smears rich in debris and inflammatory exudate containing few, if any, intact epithelial cells (Fig. 24-33). Unless specific **causative agents** (such as *Amoeba histolytica* or ova of *Schistosoma*) are identified, the cytologic diagnosis of colitis must remain nonspecific.

Histoplasmosis

Mullick et al (1996) reported two patients (one with HIV infection) with *Histoplasma capsulatum* infection, causing formation of a colonic and a rectal mass, mimicking cancer. Direct smears disclosed the presence of the fungus, described in detail in Chapter 19.

Cryptosporidiosis

The intracellular parasite *Cryptosporidium*, when ingested, infects the intestinal tract causing a diarrhea that is self-limiting in normal people but may be life-threatening in immuno-compromised patients, particularly those with AIDS (Chen et al, 2002). The diagnosis is usually established on biopsies of the intestine showing small spherical excrescences, measuring about 3 to 5 µm in diameter on the surface of the epithelial cells. There are no recorded cases of cytologic identification of the parasite.

Cytomegalovirus

In AIDS patients, involvement of the colon by this virus is not unusual. For further comments on the recognition of this virus, see above (Fig. 24-17B).

P.890

CHRONIC INFLAMMATORY DISEASES

Chronic inflammatory diseases of the bowel are caused by a number of factors, some of which are genetic, as shown with human and animal studies (summary in Podolsky, 2002). Based on clinical and pathological features, two principal forms of inflammatory bowel disease are recognized: **ulcerative colitis** and **Crohn's disease**. Both diseases may lead to a variety of serious complications, including colon cancer. Cytologic techniques have been extensively used in an attempt to identify early cancers in these patients.

Chronic Ulcerative Colitis

The disease usually begins in **young adults** with episodes of bloody diarrhea. The disease may be mild, limited to occasional episodes, moderate, with repeated episodes of diarrhea of longer duration, or severe in which the patients experience continuous diarrhea with numerous bloody bowel movements a day. The fully developed disease is characterized by formation of **confluent mucosal ulcers limited to** various segments of the colon. **Polypoid masses or nodules** may occur at the edge of the ulcers or in the intervening mucosa (Torres et al, 1998).

Patients with ulcerative colitis are **prone to the development of colonic adenocarcinoma**, as had been recognized many years ago (Cook and Goligher, 1975) and repeatedly confirmed (Mellemkjaer et al, 1995). It is generally assumed that colonic cancer in these patients is preceded by epithelial abnormalities which have been named "**dysplasia**," rather than "**carcinoma in situ**" (summary in Goldman, 1996). Molecular biologic investigation of lesions associated with ulcerative colitis suggested that the mechanism of cancer formation may differ from spontaneously occurring carcinomas (Greenwald et al, 1992; Odze et al, 2000).

Prevention of colonic carcinomas is the goal of treatment of chronic ulcerative colitis.

In patients with “severe dysplasia,” colectomy is performed as a precautionary measure. In such specimens, occult invasive carcinomas are sometimes found. The **recognition of “dysplasia” and its differentiation from inflammatory changes, either on colonoscopy or biopsy, often presents a major diagnostic challenge** that may benefit from cytologic examination.

Crohn's Disease

Crohn's disease is the principal disorder in the **differential diagnosis of ulcerative colitis.**

Crohn's disease is an **inflammatory disorder of unknown etiology**, but with a strong genetic component, observed mainly in **young adults but also occurring in children** (Podolsky, 2002). The disease is **not limited to the large bowel** as it may also involve the **small intestine** but may be observed in **distal organs** such as the **vulva** and even the **eye**. Contrary to ulcerative colitis which is limited to the mucosa and is diffuse, Crohn's disease is **segmental** and involves the entire thickness of the intestinal wall. **Ulcerations of the mucosa** are accompanied by a **chronic inflammatory reaction in the wall of the intestine**, with frequent formation of **granulomas**, and may lead to **fistulous tracts**. **The role of Crohn's disease as a precancerous condition is still being debated.** However, in the absence of clinical information, **the cytologic presentation of Crohn's disease involving colon may be identical to that of ulcerative colitis.**

Cytology of Chronic Inflammatory Disease of the Large Bowel

Ulcerative colitis was a natural target of investigations from the very onset of colonic cytology in the 1950s. The principal **purpose of this examination is to separate the precancerous abnormalities (“dysplasia”) from inflammatory changes on one hand and fully developed cancer on the other.** Chronic inflammatory changes cause a **“repair reaction”** in the surrounding colonic epithelium and cause **problems of interpretation** that are very similar for all glandular epithelia, such as the **endocervix, Barrett's esophagus, and gastric ulcer** (see Chap. 12; and previous discussion in this chapter).

In colonic smears, there is evidence of an **inflammatory reaction** in the form of leukocytes, fibrin and debris. **The epithelial glandular cells** are usually trapped in the exudate and may appear singly or in loosely structured clusters. **They may be distorted or damaged but usually retain their columnar shape, although they may be somewhat enlarged. Their nuclei are usually pale-staining and may contain visible nucleoli.** As a rule, there is **no nuclear hyperchromasia**. In **Crohn's disease**, the finding of **granulomas**, similar to tuberculous granulomas, may sometimes lead to a specific diagnosis.

Identification of Colonic “Dysplasia”

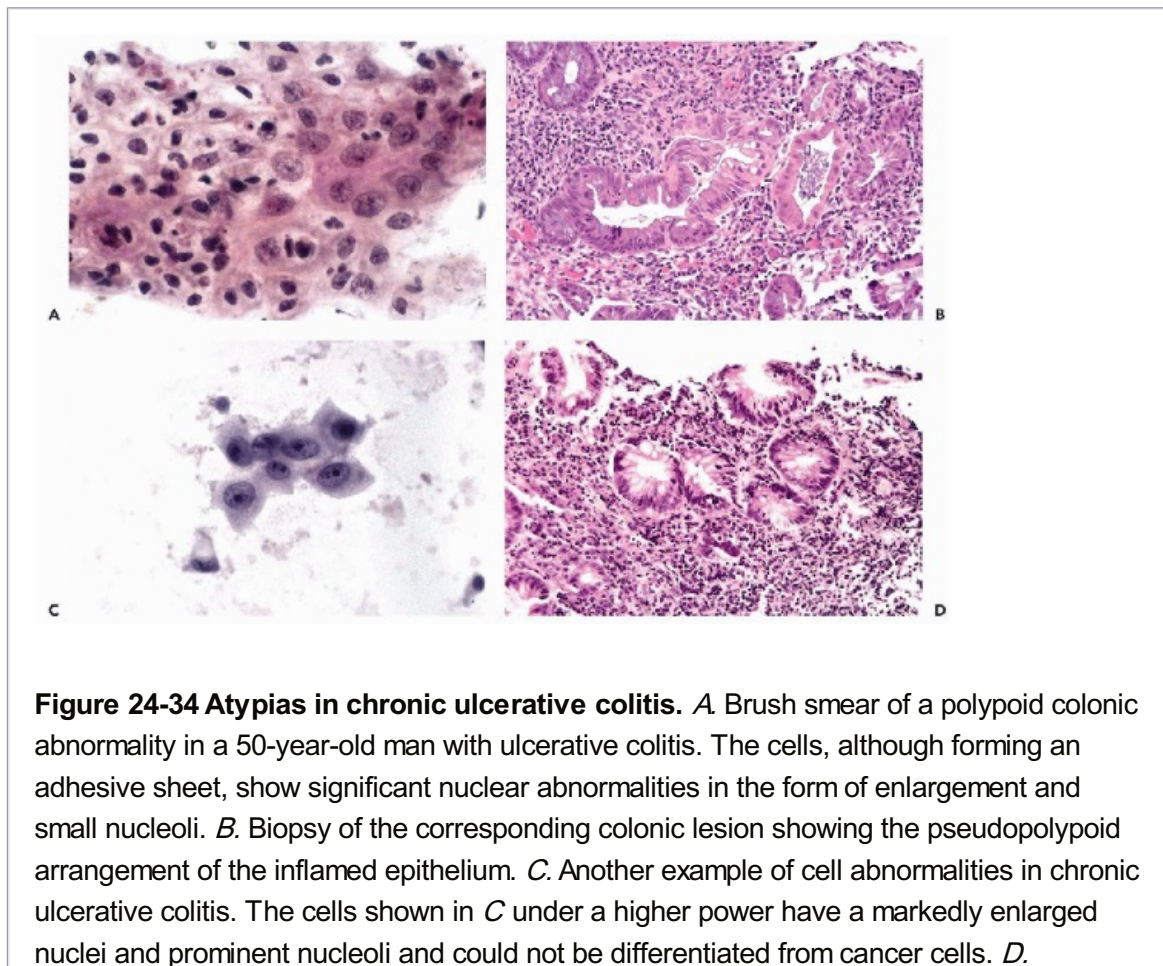

In ulcerative colitis, the task is **similar to the identification of “dysplasia” in Barrett's esophagus or stomach**, discussed in the first parts of this chapter, and is rendered more difficult by the presence of marked inflammation. Early observers (Galambos et al, 1956; Boddington and Truelove, 1956), using samples obtained by **colonic washings**, emphasized some of the diagnostic problems. In colonic washings, Galambos et al (1955, 1956) described **two types of epithelial cells: the *bland* cells and the *active* cells.** The **bland cells** were larger than normal colonic cells and had **large, clear, pale nuclei**, corresponding to findings in uncomplicated chronic ulcerative colitis. The **active cells** were also larger than normal and their **nuclei were characterized by the presence of large, sometimes irregularly shaped nucleoli.** In the presence of the active cells, **particularly if they displayed variability in**

size, the **differential diagnosis between active chronic ulcerative colitis and incipient colonic carcinoma ("dysplasia" in current terminology) was impossible**. Similar difficulties were emphasized by Raskin and Pleticka (1964) and by Prolla and Kirsner (1972). The latter authors also reported the **presence of atypical lymphocytic cells**, which may complicate the cytologic picture still further. Festa et al (1985) compared multiple cytologic samples obtained by colonic lavage and brushings from 41 patients with ulcerative colitis and observed a **wide spectrum of cytologic abnormalities, ranging**

P.891

from mild to severe atypia, to carcinoma. These observers found that the **morphologic differences between "severe atypia" ("dysplasia") and carcinoma were difficult to ascertain**. The same problem of interpretation occurred with corresponding biopsies. Six carcinomas of the colon (including two **in situ carcinomas, or "severe dysplasia,"** using current nomenclature) were accurately diagnosed. Melville et al (1988) suggested that colonic "dysplasia" could be identified in brush smears because of lesser abnormalities in nuclear configuration when compared with cells of colonic carcinoma. The illustrative evidence in support of this view was not persuasive. In my judgment, all the lesions illustrated had the appearance of cancer cells (see below).

If there is a consensus in this difficult area of cytologic diagnosis, it may be summarized as follows: **the presence of colonic epithelial cells with moderately enlarged, either hyperchromatic or clear nuclei and the presence of distinct, enlarged nucleoli may correspond to "dysplasia" or carcinoma of the epithelium of the diseased colon and should lead to a confirmatory biopsy (Fig. 24-34). The level of suspicion becomes greater if the nucleoli are not spherical but have a distorted contour.**

Corresponding area of colonic abnormality in a 49-year-old woman with a 20-year history of ulcerative colitis. Although the glands are atypical, they cannot be classified as malignant. (Courtesy of Dr. June Koizumi, New York Hospital/Cornell Medical Center, New York.)

TUMORS OF THE COLON

Adenomatous Polyps

Clinical and Pathologic Data

Adenomatous polyps are very common **benign colonic neoplasms** that may either cause rectal **bleeding or be completely asymptomatic** and are an incidental finding on endoscopic examination. The polyps may vary in size from tiny, nearly microscopic structures, to substantial tumors that may measure several centimeters in diameter. They consist of a **central connective tissue stalk** surmounted by a **crown of folded colonic epithelium** that may be either normal (see Fig. 7-1) or show varying degrees of **epithelial abnormality, such as “dysplasia” or even foci of carcinoma**. If the glands are tubular, the lesions are referred to as **tubular adenomas**. Another type of polyp, **villous adenoma, is characterized by long, delicate stalks and**

P.892

may become malignant in a high proportion of cases (Takolander, 1975). Mixed patterns of polyps occur.

Polyps are considered to be a stage in the development of colonic carcinoma (see Chap. 7 and Fig. 7-4). Prophylactic removal of polyps reduced the rate of colon cancer and was claimed to be an effective prevention measure (Winawer et al, 1996). Lane (1976) emphasized that most polypoid lesions of colon are benign. For further discussion of colonic carcinoma, see below.

Cytology

In my experience, **benign polyps of the colonic mucosa cannot be identified as such** in brush smears because the cytology is that of benign colon. Thabet and Macfarlane (1962) emphasize the presence of **slender, elongated “needle” cells and of columnar, fan-shaped cells** as characteristic of benign colonic polyps. We were unable to confirm this observation. Occasionally, colonic washings contain thick fragments of tissues that can be embedded in paraffin and identified as polyps in cell blocks.

However, **brush cytology of adenomatous polyps during sigmoidoscopy or colonoscopy, prior to biopsy or removal, may contribute to the discovery of polyps with various degrees of premalignant changes (dysplasia) or foci of carcinoma** (Halpern et al, 1997). The features of colonic “dysplasia” have been discussed above and the features of colonic carcinoma are discussed below.

Adenocarcinoma

Epidemiology and Natural History

The importance of this devastating disease has been mentioned at the beginning of this segment. It is the belief of many epidemiologists, so far unproven, that **dietary factors** are responsible for the frequency of carcinoma of colon. Other **risk factors** for colon cancer

include the presence of adenomatous polyps, particularly in familial polyposis of colon, ulcerative colitis, and family history of colon cancer (Winawer et al, 1996; Lynch and de la Chapelle, 2003). Brekkan et al (1972) observed colonic carcinomas developing at **the site of ureterosigmoidostomy**. The sequence of molecular biologic events in the genesis of cancer of the colon, as proposed by Vogelstein and Kinzer, is discussed in Chapter 7. It has been shown that regular intake of **aspirin** or the related drug **sulindac** lowers the risk of colonic cancer (Thun et al, 1991; Heath, 1993; Ladenheim et al, 1995; Wu, 2000; Sandler et al, 2003; Baron et al, 2003).

It is generally accepted that **carcinoma of the colon is preceded by precancerous lesions, such as villous adenomas, adenomatous or tubular benign polyps or epithelial lesions, classified as "dysplasia."** It is the personal view of this writer that the significance of **flat lesions of the colonic epithelium, "aberrant crypts" or flat carcinomas in situ**, which are very difficult to recognize in colonoscopy, has been **severely underestimated** as precursor lesions of colonic cancer, a view also expressed by Pretlow et al (1991). The frequency of **"aberrant crypts," lesions most likely representing early stages of formation of flat carcinomas in situ**, has been emphasized by Japanese observers performing a detailed examination of colonic epithelium, with magnifying colonoscopy and methylene blue staining (Takayama et al, 1998). The crypts usually show mutations of the *K-ras* oncogene (Pretlow et al, 1993). Incidentally, the frequency of "aberrant crypts" may be reduced after treatment with sulindac (Takayama et al, 1998).

TABLE 24-4 DUKE'S GRADING OF COLONIC CARCINOMAS

Grade	Probability of Metastases
I	18%
II	44%
III	78%

Based on study of 1,726 colonic cancers.

From Dukes CE. J Clin Pathol 2:95-98, 1949.

Histology

Carcinomas of colon appear to the endoscopist as elevated or ulcerated areas of the colon. Colonic carcinomas are **mucus-producing adenocarcinomas of varying levels of differentiation**, ranging from **well-defined glandular structures to solidly growing, anaplastic cancers, which include signet ring adenocarcinoma**. **Squamous and mucoepidermoid carcinomas** are occasionally observed (Lundquest et al, 1988), as are very rare carcinomas of other types.

Staging, Grading, and Prognosis

Duke's staging and grading, proposed in the 1930s and 1940s, shown in Tables 24-4 and 24-5, is still widely used with only minor modifications in the assessment and prognosis of colon cancer. Grading indicates a deviation from normal structure of the colonic epithelium and the degree of abnormality of cancer cells. Thus, colonic cancers closely resembling normal gland structure, lined by cells with only slight abnormalities, are tumors grade I. Solidly growing

P.893

tumors composed of bizarre or small cancer cells are grade III. The most common gland-forming tumors with intermediate abnormalities are grade II. It has been recently proposed that Duke's staging be replaced by the TNM system (Greene et al, 2002).

TABLE 24-5 DUKE'S STAGING OF COLONIC CARCINOMAS

Stage	Definition	Prognosis (5-year Survival)
A	Tumor confined to mucosa or submucosa	95%
B	Invasion of muscularis	50%-60%
C	Metastasis to regional lymph nodes	25%-30%
D	Distant metastasis	0

Based on study of 1,726 colonic cancers.

Dukes CE. J Clin Pathol 2:95-98, 1949.

Several studies have documented that measuring DNA ploidy in colonic carcinoma may have prognostic significance: diploid tumors with low S-phase appear to have a better prognosis than aneuploid tumors or tumors with high S-phase (Wolley et al, 1982; Wersto et al, 1991; Hixon et al, 1995; Takanishi et al, 1996; Cohn et al, 1997). For further comments on DNA ploidy, see Chapter 47.

Cytology

Today, most colonic carcinomas are diagnosed by colonoscopic biopsies. In the years before fiberoptic colonoscopy, Raskin and Pleticka (1964) reported that up to 20% of malignant lesions of the colon that **could not be definitely identified on the initial radiologic examination (barium enema) could be diagnosed by colonic lavage**. This skilled team diagnosed over 80% of all colonic carcinomas by cytology. Excellent results were also reported by Katz et al (1974, 1977) who used a different lavage method (see above).

With extensive use of colonoscopy, **the role of colonic cytology has been directed toward evaluating high-risk patients, such as those with colonic polyposis, ulcerative colitis, or patients at risk of recurrence at the site of prior colectomy for carcinoma** (DeLuca et al,

1974).

The **cells obtained from well-differentiated adenocarcinomas of the colon** are large, **often columnar or cuboidal in configuration, with large, sometimes irregular, hyperchromatic nuclei with prominent nucleoli, occurring singly and in clusters** (Figs. 24-35 and 24-36). Adenocarcinomas of the **rectum** are identical to colonic cancer (Fig. 24-37C,D). The cytoplasm varies in amount and is often poorly preserved. The diagnosis is based on nuclear abnormalities. Koizumi and Schron (1997) emphasized that in **metastatic colon cancer, the classical hyperchromatic nuclei may be replaced by clear nuclei with large nucleoli** (see Chap. 26 for further comments on this topic). In cell blocks of effluents, fragments of colonic cancer may be observed. It is of note that cells of colonic carcinoma may express the p21 product of the oncogene *Ha-ras*, which may facilitate their recognition in difficult diagnostic situations (Czerniak et al, 1987A).

In **signet ring cell carcinomas, large mucus vacuoles push the large, hyperchromatic nuclei to the periphery of large cells. Poorly differentiated carcinomas** may be represented in smears by **cancer cells of variable sizes, that are often approximately spherical and have large, hyperchromatic nuclei** (Fig. 24-37A,B). In the very rare **small cell carcinomas**, the tumor cells may resemble **similar tumors of lung**, discussed in Chapter 20. Silverman et al (1996) emphasized that **it may be difficult to identify small cell carcinomas in aspiration biopsies as being of colonic origin** because of their similarity to other small cell neoplasms.

Results

Today, the value of colonic cytology is primarily in the evaluation of lesions without clear-cut endoscopic or radiographic findings, and in monitoring high-risk patients. However, we have also observed several patients in whom the cytology was consistent with cancer and the initial biopsy or biopsies were nondiagnostic. Thus, cytology may serve as added insurance that a cancer of colon will not be missed. This point was emphasized by Bardawil et al (1990) who reviewed their large experience with colonoscopic brush cytology. These authors stressed the **value of a positive or suspicious cytologic diagnosis, even in the absence of initial histologic evidence of carcinoma**. The diagnoses were ultimately confirmed in all but one patient with a definitive cytologic diagnosis of cancer and in 29 of 34 patients with "suspicious" cytologic findings and initially negative biopsies. Similar results were reported by Halpern et al (1997).

Endocrine Tumors

Tumors with endocrine features, such as benign and malignant **carcinoids** and **endocrine carcinomas**, occur mainly in the small and large intestine but may also be observed in the stomach and the duodenum (Gould and Chejfec, 1978; Gaffey et al, 1990; Caplin et al, 1998). The tumors are derived from argentaffin cells dispersed in the mucosa. Most of these tumors are occult and are an incidental finding but some may have endocrine activity. We observed an example of proliferation of endocrine cells in the wall of the stomach and duodenum of a 12-year-old boy with the classical **Zollinger-Ellison syndrome** of gastric hyperacidity and ulcer formation, caused by secretion of **gastrin**. Most of such cases are associated with **gastrinomas** of the pancreas. In this case, the cells of gastrinoma formed mucosal and submucosal islets of cells or "tumorlets" (Fig. 24-38A,B). Because of their location, the "tumorlets" could not be identified on endoscopic or cytologic examination (Bhagavan et al,

1974). On the other hand, we observed a patient with a **malignant carcinoid** of the duodenum, metastatic to the lung that could be securely diagnosed on a bronchoscopic sample. Small tumor cells with small nuclei of even sizes in the smears and the cell block of the material were characteristic of the disease (Fig. 24-38C,D).

Malignant Lymphoma

The **MALT lymphomas**, some previously classified as **pseudolymphomas**, discussed above in reference to the stomach, also occur in the the small intestine and the colon. A thickening of the intestinal wall is often seen in these disorders. A point in the differential diagnosis of such lesions is **Whipple's disease**, which may be difficult to distinguish on clinical and radiologic grounds (Whipple, 1907). Whipple's disease, which may affect many other organs besides the intestine, is characterized by large **macrophages, containing a bacterium, *Tropheryma whippelii*** (Relman et al, 1992). To our knowledge, there is no record of such a lesion diagnosed by cytologic techniques.

A **large cell B-cell lymphoma of cecum** diagnosed by aspiration biopsy (FNA) was reported by Chen et al (1992).

P.894

THE DUODENUM, EXTRAHEPATIC BILE DUCTS, PANCREATIC DUCTS, AND GALLBLADDER*

ANATOMY

The **duodenum** is the first segment of small bowel, extending for about 25 cm from the pylorus

of the stomach around the head of the pancreas in a C-shaped loop to the duodenaljejunal flexure at the ligament of Treitz. It is divided into four segments, of which the second or descending segment is of special interest in cytology. It is here that the main bile and pancreatic ducts open into the duodenum through a small papilla located on the medial aspect of the duodenum.

The right and left hepatic ducts emerge from the liver and unite in the hilum approximately 1 cm from the liver to form the common hepatic duct. **The common hepatic duct** varies in length from about 1 to 5 cm (average 2.0 cm), and is 0.2 to 0.8 cm in diameter, increasing in diameter with age (Thung and Garber, 1991). **The cystic duct** of the gallbladder joins the common hepatic duct to form **the common bile duct** which is about 5 cm in length and 1 mm in diameter, and extends from above the duodenum, behind it and through the head of the pancreas into the papilla in the duodenum. In two-thirds to three-fourths of cases, the main pancreatic duct (duct of Wirsung) joins with the common bile duct as it enters the wall of the duodenum and the papilla to form a dilated common channel or ampulla (**ampulla of Vater**) with a common opening into the duodenum (DiMagno et al, 1982).

The pancreas lies in the retroperitoneum with the head of the pancreas embraced in the curve of the duodenum, the body lying behind the stomach and transverse colon and the tail extending to the hilum of the spleen (Fig. 24-39). The main pancreatic duct (duct of Wirsung) traverses the gland near its posterior surface, receiving branches from all sides, and joining with the common bile duct, or independent of it, enters the duodenal papilla. An accessory pancreatic duct (of Santorini) drains the upper part of the head of the pancreas and may join the main duct or enter the duodenum through a separate orifice.

The gallbladder is a pear-shaped sac that lies under the right lower lobe of the liver, at its inferior edge. It measures

P.895

about 10 cm in length, varies from 3 to 4 cm in width and has a 1 to 2 mm thick wall. The distal end of the gallbladder tapers to an S-shaped neck that connects with the cystic duct. The cystic duct joins the common hepatic duct to form the common bile duct. As much as a liter of bile flows each day from the liver into the gallbladder where water is absorbed, concentrating the bile into a much smaller volume that can be stored within the 50 to 70 ml capacity of the gallbladder. When a fatty meal enters the duodenum, the gallbladder contracts, emptying bile into the duodenum. Figure 24-39 shows a diagrammatic representation of extrahepatic biliary ducts and their relationship with the duodenum and the pancreas.

Figure 24-36 Colonic adenocarcinoma in colonic brushings. *A-C.* Large clusters of cancer cells with prominent hyperchromatic nuclei and nucleoli, corresponding to the colonic biopsy shown in *D*. In *A* and *B*, the cancer cells have a columnar configuration, whereas in *C*, they are cuboidal in shape. (Photographs courtesy of Dr. June Koizumi, New York Hospital/Cornell Medical Center, New York.)

HISTOLOGY

Duodenum

The villous mucosa of the duodenum undergoes gradual transition from pyloric antral epithelium to tall columnar absorptive epithelium of intestinal type with basal or suprabasal round or oval nuclei, eosinophilic cytoplasm and a deeply eosinophilic brush border at the free surface. There are interspersed goblet cells and occasional endocrine cells and Paneth cells.

Extrahepatic Bile Ducts

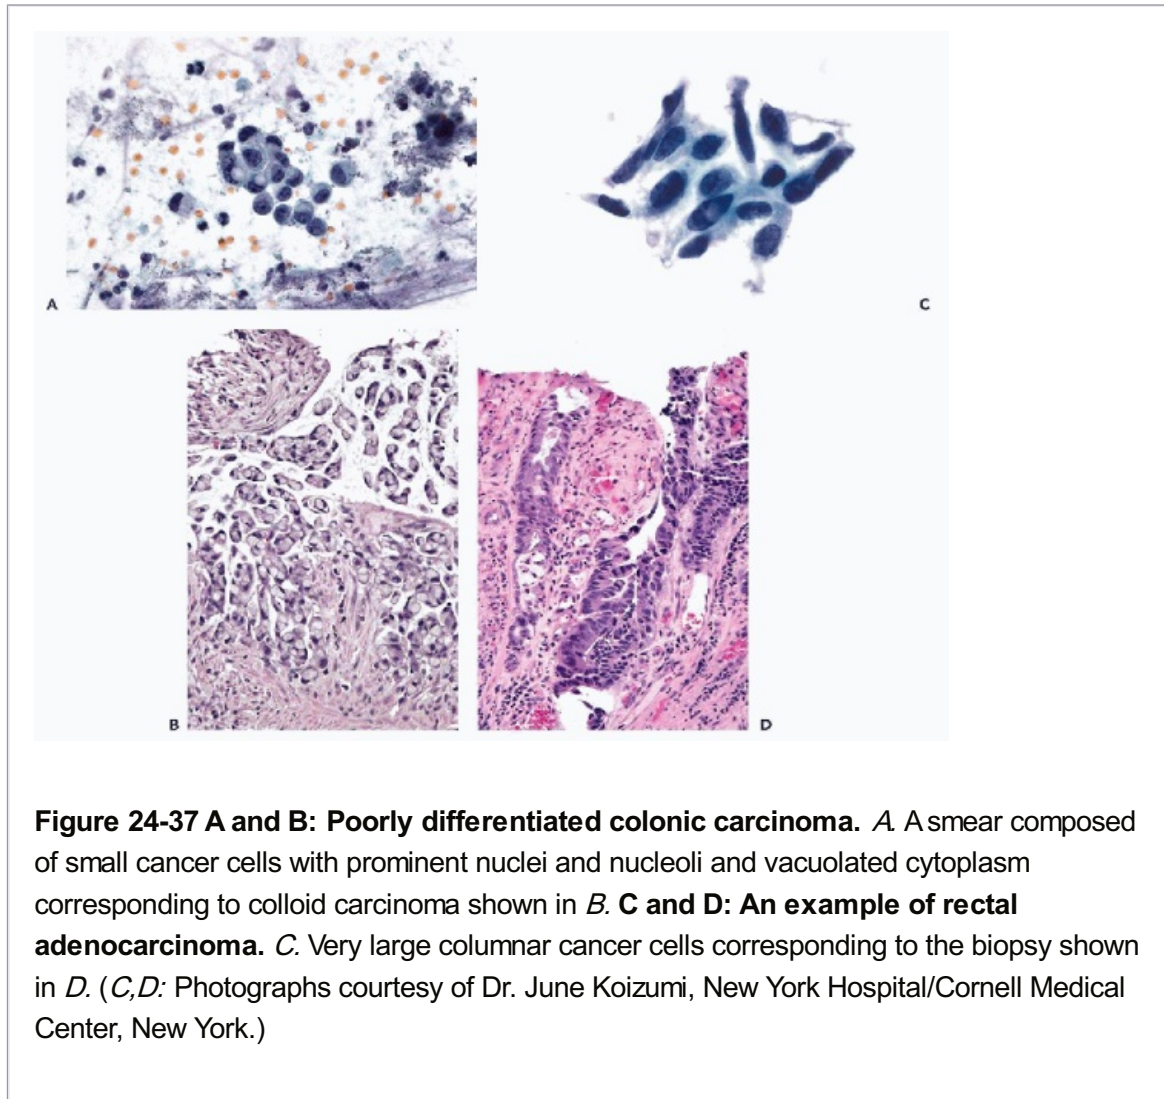

The extrahepatic bile ducts are lined by a single layer of mucin-secreting columnar epithelium with uniform, basally located oval nuclei. Nucleoli are inconspicuous or absent (Fig. 24-40A). In the absence of inflammation, there are few or no goblet cells. A few mucus-secreting glands may be present in the wall of the duct. With inflammation or irritation, the mucosa may undergo hyperplasia with epithelial atypia, increased mitotic activity, gastric or intestinal metaplasia, or sometimes mucinous or squamous metaplasia. Within the terminal portion of the common bile duct, the epithelium forms slender, branching papillary fronds that yield richly cellular brush cytology specimens.

Main Pancreatic Duct

The epithelium of the main pancreatic duct is identical to that of the common bile duct, composed of a single layer of columnar epithelial cells with lightly eosinophilic cytoplasm,

P.896

basal nuclei and occasional interspersed goblet cells. There may be reactive mucous cell metaplasia or hyperplasia, and occasionally squamous metaplasia (Fig. 24-40B).

Gallbladder

The mucosa of the gallbladder is in branching folds lined by a single layer of tall columnar epithelium with pale eosinophilic cytoplasm and basal or suprabasal smoothly contoured oval nuclei with finely textured chromatin and inconspicuous nucleoli.

INDICATIONS FOR CYTOLOGY

In skilled hands, cytology may contribute significantly to the diagnosis of cancer of the extrahepatic biliary tract, the pancreas or the ampulla of Vater. Although there are published examples of presumed precancerous lesions and early invasive carcinomas diagnosed by cytology in symptomatic patients, there is no evidence that this technique is effective in cancer detection.

Obstructive jaundice or subclinical evidence of bile duct obstruction (e.g., elevated serum bilirubin, alkaline phosphatase) is the single most important indication for endoscopic bile duct/pancreatic duct cytology. Intraoperative needle aspiration cytology of the gallbladder or imprint/aspiration cytology of the surgically resected gallbladder may have a role in detecting grossly inapparent carcinoma in patients known to be at risk (e.g., cholelithiasis; see below).

METHODS OF INVESTIGATION

Older Sampling Techniques

Cytologic examinations were first carried out on **specimens of duodenal contents**, and on direct collections of bile and pancreatic juice. We must recognize particularly the pioneering efforts of Raskin et al (1958, 1961) in urging the diagnosis of pancreatic and bile duct carcinomas by examination of exfoliated epithelial cells in aspirates of duodenal fluid. Elaborate methods of collecting duodenal contents were devised subsequently to improve specimen quality and diagnostic accuracy (Yamada et al, 1984). Except for carcinomas of the duodenal papilla or ampulla of Vater, however, these specimens usually contained very few poorly preserved tumor cells within a background of necrotic and inflammatory cellular debris. Although Dreiling et al (1960) and Goldstein and Ventzke (1968) claimed diagnostic successes in up to 75% of tumors, the duodenal aspirates generally have been disappointing. Even with improved sampling achieved by **secretin stimulation of the pancreas** (Asnaes and Johansen, 1970; Bourke et al, 1972; Yamada et al, 1984), they failed to gain wide acceptance.

P.897

Figure 24-38 Endocrine tumors of the intestine. *A,B.* Low- and high-power view of endocrine tumorlets in a 12-year-old boy with Zollinger-Ellison syndrome. The tumorlets were present within the epithelium and thus could not be identified by cytology (see text). *C,D.* Malignant carcinoid of duodenum identified in brush smear shown in *C* and corresponding to the tissue biopsy shown in *D*. The lesion metastasized to the liver.

Figure 24-39 Diagrammatic representation of the relationship of extrahepatic biliary and pancreatic ducts, the duodenum, and the pancreas.

P.898

Wertlake and Del Guercio (1976) were, perhaps, the first to demonstrate the feasibility of cancer diagnosis on specimens of bile. Later studies by Cobb and Floyd (1985) and Ishikawa et al (1988) confirmed the diagnostic value of bile cytology. Cell preservation in bile obtained during surgical exploration of the biliary tree has been surprisingly good.

Current Sampling Techniques

Endoscopic Bile and Retrograde Brush Cytology

This technique was made possible by recent advances in endoscopy and is now the most widely used and most effective method of cytologic sampling. With the introduction of endoscopic retrograde cannulation of the common bile duct (**ERCB**) through the ampulla of Vater, it became possible to obtain bile and brush specimens for cytologic examination prior to the introduction of contrast media for radiologic visualization of the duct system. Osnes et al (1975) are credited with introducing this important technique. **Under direct endoscopic visualization, a specially designed brush is threaded into the orifice of the common bile duct (or pancreatic duct) at the ampulla of Vater, and then into the hepatic ducts and/or main pancreatic duct (Fig 24-41).** When the brush is withdrawn, the **adherent cellular material is quickly and evenly spread on one or more glass slides** that are immersed immediately into a 50% alcohol fixative and sent to the laboratory. Alternatively, and preferred by us, **the brush may be placed immediately in normal saline and delivered promptly to the laboratory** for further processing (see Chap. 44). In skilled hands, the

endoscopic brushing procedure can be completed within 5 minutes. **Bile** obtained by endoscopic cannulation

P.899

as well as retrograde brush cytology can provide good sampling of well preserved cellular material from selected ducts or areas of interest. We found the brush specimens preferable to bile and consider brush samples the method of choice for cytologic evaluation of patients suspected of harboring carcinoma of the extrahepatic biliary or major pancreatic duct system.

Figure 24-40 Benign epithelia lining the biliary and pancreatic ducts. *A.* Simple columnar epithelium of the extrahepatic biliary and pancreatic ducts. The cells are mucin-secreting with pale staining cytoplasm. They may have cilia. The ovoid nuclei lying in the basal third or half of the cell have delicate chromatin and usually inconspicuous nucleoli. *B.* With inflammation or irritation, the epithelium undergoes hyperplasia with crowding of cells, goblet cell metaplasia (seen here) and increased mucin secretion.

Figure 24-41 Diagrammatic representation of endoscopic retrograde cannulation of the common bile duct (CBD) through the ampulla of Vater. Illustrated here is a tumor of the head of the pancreas that has impinged on and obstructed the CBD as it passes through the pancreas. Brush specimens obtained during the process of opening and stenting the bile duct can provide definitive evidence of carcinoma and exclude inflammatory stricture as a cause of obstruction. (Reprinted from Van Dam J, Brugge WR. Endoscopy of the upper gastrointestinal tract. *N Engl J Med* 341: 1738-1748, 1999; with permission of publishers of the *New England Journal of Medicine*.)

Percutaneous Transhepatic Cytology

When endoscopic retrograde cannulation is unsuccessful or not available, the duct system may be visualized radiographically by percutaneous injection of contrast material into dilated intrahepatic ducts, i.e., by percutaneous transhepatic cholangiography (PTC). Cytologic examinations can be carried out on bile obtained when this procedure is performed, or on subsequent bile drainage specimens. The sensitivity of this method is generally low, but Nilsson et al (1995) reported positive PTC samples in 4 of 8 patients with bile duct cancer. **Cytologic examinations should be included routinely with percutaneous transhepatic cholangiography** and may be diagnostic in some cases.

T-Tube Bile Drainage

Bile can also be a source of cytologic samples. Cressman (1977) reported the cytologic diagnosis of a common duct carcinoma on such a specimen and Muro et al (1983) reported positive cytologic diagnoses of carcinoma in 34 of 100 cases. Simsir et al (1997) found cancer cells present in the saline rinse of biliary stents from 6 of 8 patients with bile duct stenosis caused by cancer.

In an interesting technical modification, Walker et al (1982) used the percutaneous transhepatic cholangiogram and the tip of a decompressing drainage catheter to locate the site of bile duct obstruction as a **guide for percutaneous transhepatic fine needle aspiration**.

Endoscopic Ultrasound-Guided Transmural Needle Aspiration Cytology

The use of this technique is on the increase and we found it to be valuable in some cases (Brugge and Van Dam, 1999; Shin et al, 2002; Stanley, 2003) (Fig. 24-42). The cytologic sample is obtained via a special retractable needle introduced with **ultrasound guidance** during endoscopic retrograde cannulation of the common duct (Howell et al, 1992), and samples are processed according to the preference of the laboratory. Criteria for cytologic diagnosis are the same as brush cytology. **The procedure is advocated in cases of sclerosing tumors, tumors or enlarged lymph nodes extrinsic to the ducts, and tumors beyond reach of the endoscopic brush.** In expert hands, it has had good success without significant complications. Howell et al (1992) obtained positive endoscopic needle aspiration cytology with 100% specificity in 16 of 26 patients, including 10 of 19 with pancreatic carcinoma. Bentz et al (1998) reported 90% sensitivity and 100% specificity in 54 cases of periluminal lymph node aspirates, pancreatic tumors and hepatobiliary lesions. Eloubeidi et al (2003A) reported an accuracy of over 80% of small pancreatic carcinomas with only minor complications. The technique was successful in the diagnosis of a metastatic carcinoid tumor to celiac lymph nodes (Eloubeidi et al, 2003B).

Figure 24-42 Diagrammatic representation of transmural endoscopic fine needle aspiration of pancreatic tumor. If endoscopic brush sampling of the pancreatic duct is unsuccessful or if the tumor is beyond reach of the endoscopic brush, this provides an alternative means of sampling. (Reprinted from Van Dam J, Brugge WR. Endoscopy of the upper gastrointestinal tract. *N Engl J Med* 341: 1738-1748, 1999; with permission of publishers of the *New England Journal of Medicine*.)

Percutaneous fine needle aspiration (FNA) of liver and pancreas is described in Chapters 38 and 39.

CYTOLOGY OF DUODENAL ASPIRATES OR WASHINGS

Normal Duodenum

In the absence of disease, there are usually few epithelial cells in the duodenal aspirate. **Cells arising from the duodenal mucosa cannot be clearly differentiated from those of pancreatic or bile duct origin**, which are described and illustrated below. All occur singly or in clusters and have a **columnar configuration with a striated or occasionally ciliated flat luminal surface**. The cells are large and measure 20 to 30 μm in length. Nuclei are round, usually basally placed, and have delicate vesicular chromatin. They often have a small nucleolus. When seen on end in flat clusters, the cells are arranged in a **honeycomb pattern** with the nucleus centrally located within the cytoplasm. In single cells or cells in groups seen from the side, the cytoplasm is generally opaque or sometimes finely vacuolated and may be eosinophilic or cyanophilic. **Goblet cells** may be present singly or in clusters among the columnar cells. They are of approximately the same size as the columnar cells and have a basally placed nucleus with characteristic finely vacuolated supranuclear cytoplasm. In the absence of active disease, the epithelial cells are usually well preserved. The smears contain few macrophages or leukocytes.

Inflammatory Processes

In the presence of active inflammation, most commonly **peptic ulcer, duodenitis** or **pancreatitis**, there is a marked

P.900

increase in the cellularity of the aspirate. Exfoliated epithelial cells are not well preserved. Most are small and rounded with granular or vacuolated cytoplasm and degenerated nuclei undergoing karyorrhexis or karyolysis and may resemble macrophages (Fig. 24-43). There are numerous stripped or “naked” nuclei, and often a large number of leukocytes and phagocytic macrophages. Orell and Ohlsen (1972) considered **large numbers of stripped nuclei to be characteristic of chronic pancreatitis**. Cheli et al (1974) described an increase in goblet cells in chronic duodenitis.

Parasites and Other Microorganisms

A number of microorganisms have been detected in the duodenal aspirate, including most commonly, the parasite *Giardia lamblia* (see Fig. 24-17A). Joste et al (1999) reported finding *microsporidia* spores in bile from a young man with AIDS and symptoms of cholangitis. The spores are tiny and would be extremely difficult to detect in an inflammatory specimen, even with the help of a silver stain. Papillo et al (1989) identified ova of the liver fluke *clonorchis sinensis* in bile from a patient with cholangiocarcinoma. Wee et al (1995) identified **acid fast bacilli** in T-tube drainage of bile from a patient with hepatobiliary tuberculous pseudotumor, and Kimura et al (1997) detected the fungus, *trichosporon* in bile.

Malignant Tumors

Duodenal aspirates or washings are a poor medium for diagnosis of tumors of the pancreaticobiliary region, particularly when compared with direct brushings, described below. The yield of tumor cells is small and their preservation is generally poor. Only in the rare carcinomas of the **papilla of the ampulla of Vater** is the yield of cancer cells better. The features of the cancer cells are the same as described below for direct brushings of the ducts.

Figure 24-43 Exfoliated degenerating epithelial cells associated with duodenal

ulceration and inflammation. The cells are rounded with finely vacuolated cytoplasm and pyknotic or lysed nuclei, some resembling macrophages. Leukocytes and red blood cells are few here but are typically present and numerous.

BRUSH CYTOLOGY OF EXTRAHEPATIC BILE AND PANCREATIC DUCTS

Normal Ducts

In the absence of disease, a technically satisfactory **brush** cytology specimen yields abundant benign ductal epithelium, much of which is in irregularly configured flat sheets of cells (Fig. 24-44A) that may be accompanied by granular crystals of yellow or green **bilirubinate** (Fig. 24-44B), **cholesterol crystals** or **crystalline calcium carbonate**. The epithelial cells are in coherent **plaques or strips**; seen on end, the cells comprising such plaques form a **“honeycomb” pattern**, not unlike the pattern of endocervical or gastric cells. A strip of epithelium seen from the side has much the same appearance as the columnar epithelium of bile duct in a histologic section (Fig. 24-44A). Single cells and loose clusters of a few cells are almost always present as well. Some crowding of benign cells caused by inadequate spread of the sample may occur. **“Feathering” of cells** is a brush-induced artifact (Fig. 24-44C) that should not be mistaken for cancer.

The epithelial cells are **columnar** or **cuboidal** with generally pale-staining cytoplasm and a suprabasal **spherical or ovoid nucleus** with delicate chromatin and one or two tiny nucleoli. There may be occasional cytoplasmic vacuoles. There are also tissue fragments containing groups of small, spindly cells with darkly-stained elongated nuclei which are most likely stromal cells (Fig. 24-44D). In the absence of active inflammation, there are few inflammatory cells.

In specimens of **bile**, there are fewer intact plaques of cells and, though sometimes cell preservation is suboptimal, it is adequate for diagnosis in most cases. Cellularity and cell preservation may be improved by saline irrigation of the duct at the time bile is collected (Nishimura et al, 1973).

Atypical Ductal Epithelium

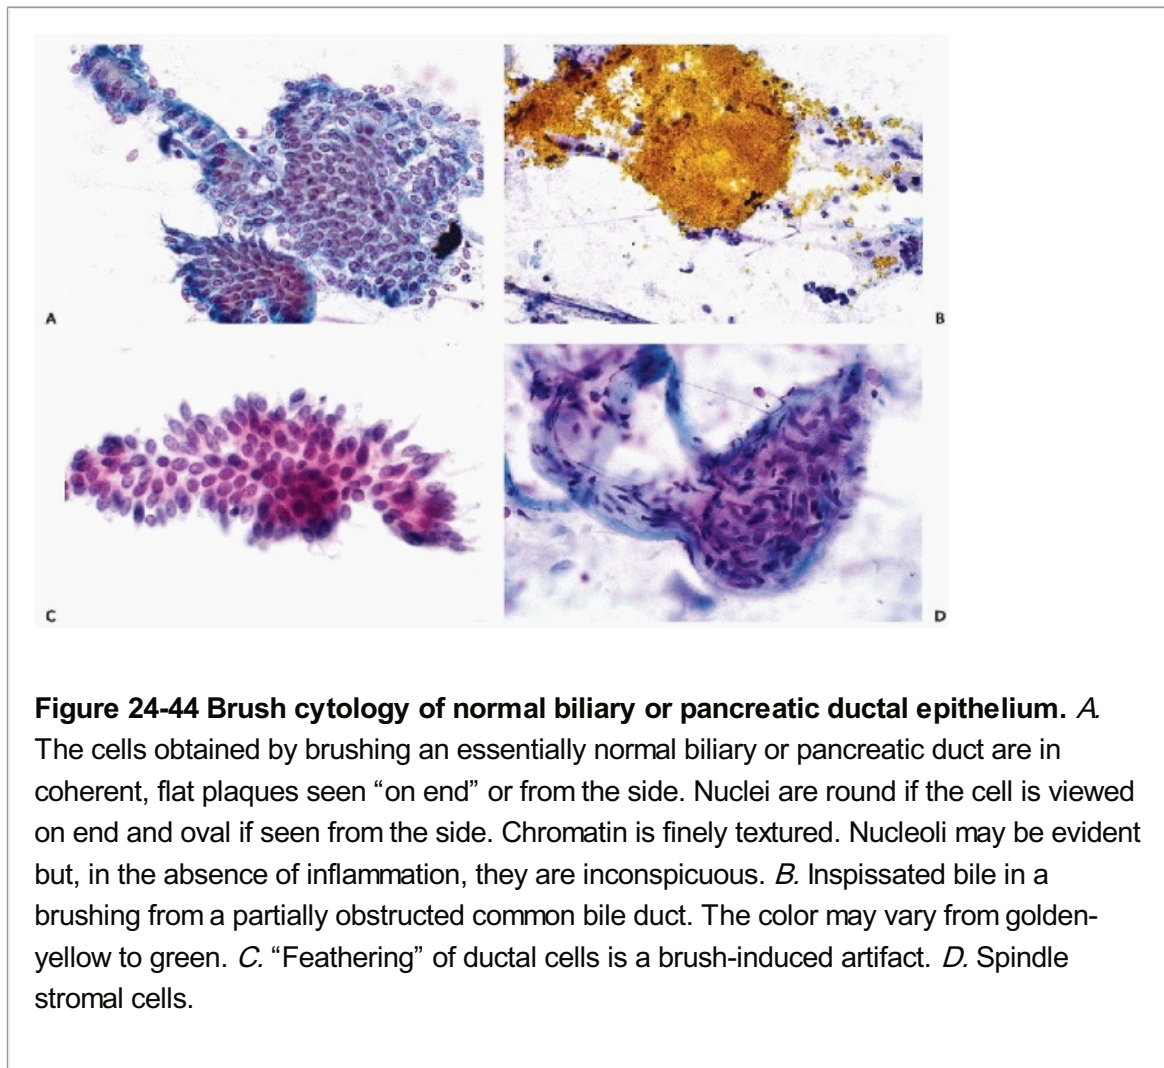

Under a variety of circumstances, some known, such as stones or inflammation, and some unknown, **clusters** of ductal cells may show **nuclear atypia** in the form of isolated enlarged and hyperchromatic nuclei, some showing conspicuous but small nucleoli (Fig. 24-45). The clusters are generally orderly and flat, sometimes infiltrated by polymorphonuclear leukocytes (Fig. 24-45D) and **are not accompanied by single clearly malignant cells**. The interpretation of such atypical clusters may be very difficult, particularly in the presence of obstructive jaundice, as they may reflect changes at the periphery of a carcinoma.

A careful review of the clinical and roentgenologic data is indicated in such cases to rule out **bile stones, an inflammatory process**, or sometimes **extrinsic pressure** on the biliary tree. It has been our policy to report such findings in a conservative fashion, admitting the limitations of cytology in such cases and suggesting a careful follow-up of patients, with additional sampling.

BILE DUCT CARCINOMA

Carcinomas of the extrahepatic bile ducts are relatively uncommon. Edmondson (1967) found 53 cases in a series of

56,000 autopsies (0.1%); 1,380 cases were recorded by the Surveillance, Epidemiology and End Results (SEER) program of the National Cancer Institute over a recent 10-year period in the United States, an estimated incidence of 0.54 cases per 100,000-population (Albores-Saavedra et al, 2000). Most carcinomas are no longer surgically resectable when diagnosed and survival is short. Yet these are potentially curable tumors if confined to the organ of origin and they are amenable to cytologic diagnosis by endoscopic brushing. In fact, short of surgical exploration, endoscopic brush cytology is the only effective means of early diagnosis and is, therefore, of particular interest to the gastroenterologist and cytopathologist.

Extrahepatic bile duct carcinomas occur in patients in their 60s and 70s, are very rare before 40 years of age, and are somewhat more common in men than women. More than 90% of patients present with **symptoms of biliary obstruction**, e.g., jaundice and pruritus. However, tumors narrowing, but not obstructing, the common hepatic or bile duct (see below) or located in the hilum of the liver proximal to the common hepatic duct (**Klatskin's tumor**), may not cause jaundice. About one-third of the patients have a history of cholelithiasis and a surprising number have a history of prior biliary tract surgery. While there are many conditions that may cause biliary obstruction and jaundice, the most important differential diagnosis of bile duct carcinoma is inflammatory or traumatic **stricture** of bile ducts and **primary sclerosing cholangitis** (see below).

Histology

Carcinomas of extrahepatic bile ducts may grow as polypoid intraluminal tumors but more commonly are nodular or constrictive and diffusely infiltrating the wall of the duct. Three quarters of all extrahepatic bile duct carcinomas are well to moderately differentiated **adenocarcinomas** (Fig. 24-46) and another 4% to 5% each are **adenosquamous**, **papillary** or **undifferentiated carcinomas** (see below). **Small cell**, **mucinous** and **signet ring carcinomas** each constitute less than 2% of the bile duct carcinomas.

Brush Cytology

Most carcinomas of the extrahepatic bile ducts are moderately well differentiated and cytologic features are similar to those of other ductal carcinomas. The most abundant

P.902

cell samples are obtained from the polypoid tumors. The **tumor cells may be single but also form loosely structured groups that are piled up in three dimensional clusters or disordered flat sheets exhibiting architectural atypia** (Fig. 24-47). They may also form **small papillary clusters, cell-in-cell groups, or occasionally acinar structures** (Fig. 24-47D). Cytologic atypia varies depending upon tumor grade. It is most marked in high-grade carcinomas (Fig. 24-48), and best demonstrated in the few single tumor cells that accompany the cell clusters. Whereas in well-differentiated carcinomas the tumor cells are either somewhat smaller or somewhat larger than normal, in high-grade tumors the tumor cells are three or four times larger than normal may be huge and include mono- or multinucleated giant cells. The cell size and nuclear pallor may increase still further if fixation is delayed even briefly (Fig. 24-48D).

Figure 24-45 Inflammatory atypia in brushings of common bile duct. *A* Brushing from Ampulla of Vater showing atypia in a patient with gallstones. Though nuclei are enlarged, the epithelial cells form coherent, flat sheets and clearly benign. Nuclear chromatin is delicate and nucleoli are visible but not prominent. *B*. Atypia is more marked in these cells from the same patient. The cells are swollen, with enlarged vesicular nuclei and abundant pale-staining mucinous cytoplasm, and could be considered suspicious. However, nuclear chromatin is delicate and nucleoli, though evident, are not conspicuous. *C*. Reactive epithelial changes in an 82-year-old man with obstructive jaundice. Note the

presence of bile pigment. *D.* ThinPrep, same case. There is crowding of cells, mild nuclear hyperchromasia and occasional nuclei with nucleoli. Leukocytes infiltrate the epithelium which retains coherence including well-oriented columnar epithelium at the periphery.

Occasional tumor cells may exhibit cytoplasmic vacuolization and focal mucin secretion, but **mucinous and signet cell carcinomas** are uncommon and yield cells similar to those from other tumors of similar histology observed in other organs.

The most important and most difficult diagnostic task is in the **differential diagnosis of orderly, low-grade adenocarcinoma versus inflammatory or reactive epithelial atypia**, discussed above. The columnar epithelial cells in these two conditions may be similar and nuclear abnormalities of well differentiated carcinomas may not be obvious. However, the tumor cells usually exhibit slight nuclear enlargement, often with irregular nuclear configuration and molding, increased nuclear/cytoplasmic ratio, coarse chromatin clumping and hyperchromasia with visible or even prominent nucleoli. One other important feature in our experience is the **3-dimensional loose aggregation and single cells of carcinoma compared with the flat plaques and fewer single cells of benign reactive atypias**. Benign ductal epithelium is almost always present in the brushings and is useful for comparison with suspect cells. Admittedly, in some cases the distinction cannot be securely made and may require additional sampling.

Bile

Specimens of bile were studied by Nakajima et al (1994) who selected key criteria for diagnosis of carcinoma that

P.903

were similar to cell features described above, and included **loss of honeycomb arrangement, enlarged nuclei, loss of polarity, bloody background and cell-in-cell grouping**. In bile cytology obtained by **transhepatic needle aspiration**, the presence of mucicarmine positive droplets in the tumor cells strongly favors cholangiocarcinoma or metastatic adenocarcinoma over hepatoma. While immunocytochemistry may eventually prove of value, in our experience to date and that of others (Stewart and Burke, 2000), these markers are still of limited value (see below).

Figure 24-46 Cholangiocarcinoma. *A.* Gross photograph showing carcinoma at the junction of the cystic duct with the common bile duct in a 54-year-old woman with obstructive jaundice. The cystic duct wall is thickened and mucosal folds obliterated. *B.* At low magnification, the ductal epithelium is replaced and the lumen narrowed by the tumor. *C,D.* At higher magnification, the carcinoma is moderately well differentiated, papillary and mucin-secreting.

RARE TUMORS OF BILE DUCTS

Granular cell tumors of the biliary ducts have been described (Coggins, 1952; Eisen et al, 1991; Butler and Brown, 1998; te Boekhorst et al, 2000; Martin and Stulc, 2000). The cytology of these tumors is discussed in Chapters 20 and 29. A **carcinoid tumor** forming metastases was described by Eloubeidi et al (2003B). A similar case is illustrated in Figure 24-38.

On rare occasions, **squamous carcinoma** or **mixed adenosquamous carcinoma** may arise in the bile duct and cytology samples then contain single or small groups of **keratinized squamous cancer cells** with coarsely textured, irregular, hyperchromatic nuclei and opaque eosinophilic or orangeophilic cytoplasm. Hughes and Niemann (1996) reported two cases of adenosquamous carcinoma diagnosed on brush cytology specimens. When unusual cytologic findings are encountered, one must always consider the possibility of **metastatic carcinoma** to the liver or adjacent hilar lymph nodes causing obstructive jaundice. Dusenberry (1997) reported a case of **hepatoma causing bile duct stricture** in which brushing cytology revealed endothelial cells surrounding clusters of malignant cells, a cytologic feature characteristic of well differentiated hepatoma (see Chap. 38). **Other rare malignant tumors** of the pancreaticobiliary system that deserve brief mention include malignant melanoma and sarcomas (embryonal rhabdomyosarcoma). They are very rare at this site and the cytology of these tumors at other sites is described elsewhere in this text.

PANCREATIC DUCT CARCINOMAS

Brush cytology of pancreatic duct carcinoma is the same as that of extrahepatic bile duct carcinoma (compare Figs. 24-47 and 24-48). In patients whose main pancreatic duct

is blocked by carcinoma of the head of the pancreas, it may be possible to cannulate the duct for brushings. If not, a good specimen can be obtained from the dilated distal duct by ultrasound-guided endoscopic transmural needle aspirate (Fig. 24-49). Occasionally, pancreatic duct brushings may result in an unusual diagnosis. Figure 24-50 shows an example of a rare **clear cell carcinoma of pancreas** identified in a brush specimen.

Figure 24-47 Adenocarcinoma in brushing of common bile duct. A-C. Cells are enlarged, crowded, overlapping and disarranged with relatively large, coarsely textured, hyperchromatic nuclei. Nucleoli are visible, and may be prominent. Note the gland-like formation in C. D. ThinPrep from another case showing cells of adenocarcinoma.

Excellent diagnostic results have been reported with the use of **endoscopic ultrasound devices guided by thin needle aspiration biopsies** (Shin et al, 2002; Eloubeidi et al, 2003A; Stanley, 2003).

PRECANCEROUS LESIONS

Single or multiple areas of **carcinoma in situ (“high-grade dysplasia”)** and **lesser degrees of epithelial abnormality (“moderate or mild dysplasia”)** are commonly present in the **extrahepatic bile duct and pancreatic ducts adjacent to or distant from carcinoma.**

Albores-Saavedra and Henson (1986) found carcinoma in situ or dysplasia in mucosa adjacent to the invasive carcinoma in 6 of 61 cases. In small series of cases reported by others, precancerous changes accompanying carcinoma ranged from one-third (Davis et al, 1988) to 45% (Laitio, 1983). Suzuki et al (1989) found carcinoma in situ in 5 of 12 cases. These precursor lesions may be responsible for the high rate of local recurrences following resection of localized tumor. They are characterized in histologic sections by cellular and nuclear abnormalities, hyperplasia and loss of the normal orderly arrangement of the epithelium in an otherwise intact mucosa (Fig. 24-51A,D).

Brush Cytology

Criteria for identification of borderline or precancerous lesions of the main pancreatic and bile ducts are still speculative. They are presumed to be the source of suspicious, though not frankly malignant, cells that commonly accompany the cancer cells in a brush specimen. In several cases seen by us, there were fairly **orderly strips or plaques of columnar or cuboidal epithelium with interspersed large, hyperchromatic nuclei** (Fig. 24-51B,C). In other cytology specimens, dislodged sheets of cells presumed to be from sites of carcinoma in situ have had **overlapping, slightly enlarged but smoothly contoured nuclei with granular chromatin, minimal or no hyperchromasia and visible nucleoli**. Distinguishing low level dysplasia from marked inflammatory atypia is difficult in the absence of clearly malignant cells. This level of cytologic abnormality warrants repeat examination, which has a high probability of yielding diagnostic cancer cells (see above and Fig. 24-45 for further comments on atypia of bile duct epithelium).

P.905

Figure 24-48 Carcinoma of common bile duct in a 77-year-old man. *A.* An area of the tumor showing a focus of anaplastic adenocarcinoma next to a well-differentiated tumor. *B.* A cluster of disarranged, overlapping, predominantly columnar malignant cells with enlarged, hyperchromatic nuclei. *C.* Loosely dissociated cells of adenocarcinoma. *D.* Drying artifact in a brushing of common bile duct carcinoma. Cells are increased in size and pale staining with smudging of chromatin and loss of nuclear detail. (*B,C:* Diff-Quik, Dade Behring Inc., Deerfield, IL.)

Figure 24-49 Keratinizing squamous carcinoma of bile duct. *A.* Histology. *B.* Endoscopic brush cytology. The cancer cells have densely eosinophilic cytoplasm and hyperchromatic nuclei, resembling squamous cancer cells of other sites. The presence of a few such cells among less differentiated malignant cells is sufficient for diagnosis and classification.

P.906

Figure 24-50 An uncommon clear cell carcinoma of pancreas. *A.* Gross appearance of the carcinoma arising in the head of the pancreas at the point of junction of the obstructed and dilated common bile with the main pancreatic duct. *B.* Histology of the clear cell carcinoma compared with normal pancreatic parenchyma. The tumor cells are large with abundant, pale-staining “clear” cytoplasm. *C,D.* Tumor cells with abundant pale and delicate cytoplasm and large, irregular hyperchromatic nuclei in a brush cytology specimen form primarily gland-like clusters.

CYTOLOGY OF BILE OBTAINED BY PERCUTANEOUS TRANSHEPATIC ASPIRATES

Bile obtained by percutaneous aspirations contains exfoliated and abraided clusters and single cells of bile duct and hepatic epithelium. Rupp et al (1990), using a device described by Portner and Koolpe (1982), successfully identified 31 of 38 carcinomas, including 21 of pancreatic, 6 of bile duct, 1 of ampullary, 1 of gallbladder origin, and 2 metastatic carcinomas. The specimens varied in cellularity and cellular composition, in degree of cellular preservation and in the presence of blood and inflammatory cells. Bile provides a harsh environment and cellular preservation of epithelium that is not freshly exfoliated may be suboptimal. The reader should be cautioned that, in the presence of chronic obstructive jaundice, the ductal epithelium of bile-filled, distended hepatic ducts and the surrounding hepatocytes may undergo reactive and

proliferative changes that mimic carcinoma. However, nuclear hyperchromasia and structural abnormalities of chromatin seldom approach the level of bile duct carcinoma as described above for brush specimens.

ENDOSCOPIC TRANSMURAL NEEDLE ASPIRATION CYTOLOGY

Cytologic criteria for diagnosis are the same as for percutaneous fine needle aspirates of adenocarcinoma (see Chaps. 38 and 39). The presence of cancer cells in a background of mucin is highly suggestive of an intraductal mucinous adenocarcinoma.

VATERIAN TUMORS

Tumors of the **ampulla of Vater** and/or the **duodenal papilla** are uncommon. They generally present with intermittent jaundice and fever, presumably due to tumor necrosis, and they **mimic the symptoms of biliary calculus**. Obstruction of bile and pancreatic ducts occurs early and duct dilatation often is evident before there is tumor mass. The tumors may be benign (ampullary adenomas) or malignant (ampullary carcinomas).

P.907

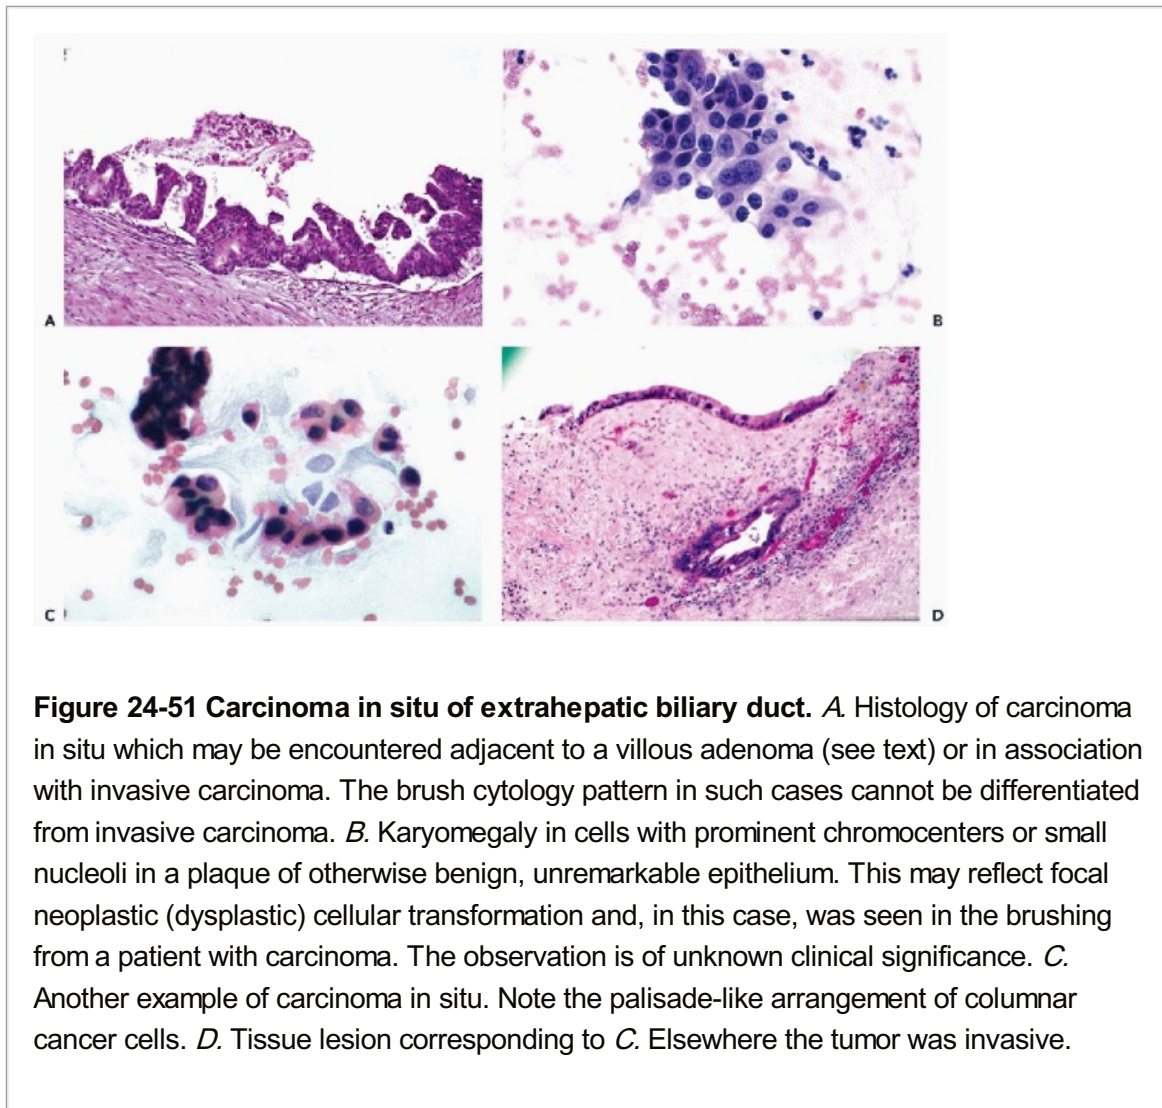

Figure 24-51 Carcinoma in situ of extrahepatic biliary duct. *A.* Histology of carcinoma in situ which may be encountered adjacent to a villous adenoma (see text) or in association with invasive carcinoma. The brush cytology pattern in such cases cannot be differentiated from invasive carcinoma. *B.* Karyomegaly in cells with prominent chromocenters or small nucleoli in a plaque of otherwise benign, unremarkable epithelium. This may reflect focal neoplastic (dysplastic) cellular transformation and, in this case, was seen in the brushing from a patient with carcinoma. The observation is of unknown clinical significance. *C.* Another example of carcinoma in situ. Note the palisade-like arrangement of columnar cancer cells. *D.* Tissue lesion corresponding to *C.* Elsewhere the tumor was invasive.

While **villous adenomas of the ampulla are benign** (Fig. 24-52A), they are considered to be **precursors of adenocarcinoma** (Rosenberg et al, 1986). Foci of carcinoma may be found within the larger adenomas (>12 mm), and co-existing adenoma is frequently found in

conjunction with, or at the margins of, adenocarcinoma (Kozuka, 1982; Yamaguchi, 1987; Qizilbash, 1990). **Brush cytology findings of villous adenomas** of the ampulla of Vater were described in four cases by Veronezi-Gurwell et al (1996). The distinguishing feature was the presence of **elongated, slender columnar cells** with elongated, basally placed nuclei, finely granular chromatin and one or more small nucleoli that were either single or formed small groups or sheets (Fig. 24-52B). There may be accompanying bile pigment. In our own experience, the exfoliated epithelial cells closely match normal ductal epithelial cells and we found no reliable cytologic criteria for diagnosis of villous adenoma. The epithelial cells in such cases appeared more rounded and somewhat less uniform than normal, though still columnar or cuboidal. The most useful diagnostic feature was **a grouping of tumor cells into loose three dimensional aggregates** rather than flat clusters.

Ampullary carcinomas yield cells in brushing specimens similar to colonic carcinoma, though usually with less necrosis (see Figs. 24-36 and 24-37). An uncommon tumor that has been observed in the ampulla is a variant of islet cell tumor, a **somatostatinoma**, diagnosed by endoscopic fine needle aspiration cytology by Guo et al (2001).

NONNEOPLASTIC OBSTRUCTIVE PROCESSES

The most common nonneoplastic conditions obstructing the extrahepatic bile ducts are **biliary calculi, bacterial cholangitis, late effects of a stent, and primary sclerosing cholangitis (PSC)**. Of these, PSC presents the cytopathologist with the **most difficult and most important differential diagnosis** for bile or pancreatic duct carcinoma.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis is a chronic, progressive, cholestatic inflammatory disease of the biliary duct system, occurring mainly in men up to the age of 40. The clinical presentation with symptoms and signs of progressing obstructive

P.908

jaundice strongly suggest bile duct or pancreatic duct cancer, particularly in the absence of stones. Early in the disease, patients may be asymptomatic or have mild nonspecific symptoms and present with slight elevations of bilirubin or alkaline phosphatase, indicating bile duct obstruction.

Figure 24-52 Villous adenoma of duodenum. *A.* Histology. *B.* Cytology brushings showing elongated epithelial cells (see text). We have not encountered such cells in brushings from a villous adenoma but have seen them in brushing from villous mucosa accompanying carcinoma, as shown here. Note the bile pigment.

The etiology of PSC is unknown but is probably an autoimmune disease. ANCA (antineutrophil cytoplasmic antibodies) are found in most of these patients. PSC is frequently **associated with idiopathic chronic inflammatory bowel disease, most commonly ulcerative colitis**.

Intrahepatic bile ducts are involved as well as the extrahepatic duct system and, in some cases, the gallbladder and pancreatic ducts are also involved. The most important complications of PSC are complete obstruction of the common bile duct, bile duct carcinoma which develops in 5% to 10% of these patients, and liver failure late in the course of the disease. In a case seen by us, there was obstruction of the pancreatic duct leading to total atrophy of the exocrine pancreas, sparing the endocrine pancreas. Enns et al (2003) reported that endoscopic retrograde cholangiopancreatography (ERCP) may result in a clinical improvement and that bilirubin levels are an important variable in assessing the status of the patient.

Histologically, the extrahepatic bile ducts exhibit chronic inflammation, fibrosis and stenosis, often with mucosal ulceration.

The experience with **cytologic sampling** of bile ducts in PSC is limited. **Brush cytology** specimens from PSC show **epithelial atypia** with some **crowding and overlapping of nuclei in sheets of cells**, moderate nuclear enlargement and hyperchromasia, and small nucleoli (see Fig. 24-45). In some cases, these cytologic abnormalities may raise suspicion of carcinoma. **Immunocytochemical stains** for p53 and carcinoembryonic antigen (CEA) that are positive in carcinoma and negative or weak in PSC, have been proposed for differential diagnosis. We found them to be of limited value. The differential diagnosis is complicated even more because some of the patients with abnormal cytology were found to have flat or papillary **“dysplasia,” or carcinoma in situ** of the mucosa of the bile duct on careful histologic study (Ludwig et al, 1992). At autopsy of patients with PSC, the prevalence of carcinoma reaches 42% (Rosen, et al, 1991).

DIAGNOSTIC ACCURACY OF ERBC

The sensitivity and specificity of cytologic diagnosis by **endoscopic retrograde brush cytology** (ERBC) is highly dependent on the location of the tumor (common bile duct or pancreatic duct), sampling and quality of specimen obtained by the endoscopist and, to a lesser extent, by tumor grade. Brush cytology or ultrasound-guided specimens, obtained by a skilled and experienced endoscopist, properly smeared, fixed and stained, can generally be diagnosed with a high degree of accuracy.

In an early prospective study comparing bile cytology vs. bile duct brushing, Kurzawinski et al (1993) reported positive diagnoses of carcinoma in 69% of 46 patients by brushing and, in 26% of the same group, by bile cytology. There were no false-positive diagnoses and none of those with positive bile cytology had negative brushing cytology.

In a more recent evaluation of bile duct brushing specimens from 131 patients who had biopsy documentation of carcinoma, Kocjan and Smith (1997) achieved sensitivity of 78% with 100% specificity. They reviewed an earlier series to which we have added reports summarizing sensitivity shown in Table 24-6.

In an unpublished series from our own laboratory, Khalbuss and Hussain reviewed 276 bile duct cytology specimens from 187 patients with biliary stricture, of whom 19 had unequivocal evidence of a malignant tumor and 20 were suspicious. All positive cases were confirmed by surgery and pathology (9) or clinical course (10). Of the 20 suspicious cases, 13 had malignant

tumors (10 primary in the cholangiopancreatic system) and 2 patients had ampullary villous adenomas. Twelve of 148 patients (8%) with negative brushing cytology proved to have a malignant tumor in the cholangiopancreatic tree (6 bile duct carcinomas; 3 pancreatic carcinomas; 3 ampullary carcinomas).

P.909

TABLE 24-6 BILE DUCT BRUSHING SPECIMEN SENSITIVITY FROM PUBLISHED STUDIES*

Year	Authors	No.	Cases Carcinoma	Cytologic Specimen	Sensitivity
Sensitivity Less Than 50%					
1985	Cobb & Floyd	18	Bile duct	Bile	48%
1990	Rabinovitz et al	37	Bile duct	Brushing	
				1st brush	40%
				3rd brush	82%
1991	Foutch et al	17	Bile duct	Brushing	33%
				Bile	6%
1991	Desa et al	24	Bile duct	Brushing	40%
		80	Bile duct	Bile	30%
1994	Ryan and Baldauf	48	Pancreaticobiliary	Brushing	42%
1995	Layfield et al	36	Pancreatic and bile ducts	Brushing	44%
Sensitivity Greater Than 50%					
1977	Harada et al	66	Bile duct	Endoscopic aspirate	83%

			Ampulla	Endoscopic aspirate	100%
1989	Sawada et al	72	Pancreatic	Brushing	85%
1990	Rupp et al	35	Pancreatic and bile duct	Brushing	80%
1990	Scudera et al	20	Pancreatic and bile duct	Brushing	60%
1990	Venu et al	53	Pancreatic and bile duct	Brushing	70%
1991	Witte and Langer	211	Pancreatic and bile duct; and papilla	Brushing	59%
1993	Kurzwinski et al	42	Bile duct	Bile only	33%
		39	Bile duct	Bile & brushing	69%
1996	de Peralta- Venturina et al	55	Pancreaticobiliary	Brushing (68 cases) and bile (8 cases)	100%
1997	Kocjan and Smith	131	Bile duct	Brushing	78%
1999	Trent et al	31	Bile duct	Brushing	80%
* Specificity was 98%-100% in most series.					

Kocjan and Smith (1997) **attributed false-negative results to four factors:**

- **Poor sampling on brushing or endoscopic needle aspiration.** These authors suggested that pushing rather than pulling the brush gave better diagnostic results.
- **Overlooking single malignant cells** hidden in a background of inflammatory and necrotic cellular debris
- **Poor recognition of precancerous lesions**
- **Cytologically bland low grade papillary and mucinous tumors**

GALLBLADDER

Indications for Cytology

The purpose of cytologic sampling of the gallbladder is to rule out a primary malignant tumor. The prerequisite for sampling is an enlarged gallbladder, preferably palpable through the abdominal wall. Gallbladder enlargement may have many causes, such as acute or chronic cholecystitis or cholelithiasis, which usually cause clinical symptoms. Painless enlargement may be caused by a cancer of the head of the pancreas obstructing the common bile duct and causing retrograde bile stasis (**Courvoisier's gallbladder**). Primary gallbladder cancer causes symptoms only if associated with stones or in late stages of spread to adjacent organs.

Techniques

Cytologic examination of bile collected in the duodenum or from the common bile duct is of limited value in reference to the gallbladder (Akosa et al, 1995). The gallbladder is out of reach of retrograde endoscopic brushing. The most useful cytologic samples are obtained in thin **needle aspirates of bile from the gallbladder**, either under direct vision at laparotomy or laparoscopy, or by ultrasound-guided percutaneous needle aspiration (Zagar et al, 1991). Ishikawa et al (1988) reported that cytologic sampling could be further improved by saline-irrigation at the time of collection. The experience with these techniques in the US is minimal. **Imprint cytology of the gallbladder** was recommended by Vallilengua et al (1995) for detection of dysplasia and occult carcinomas in cholecystectomy specimens of patients at risk.

P.910

Inflammatory Lesions

The most common pathologic process involving the gallbladder is chronic cholecystitis, with or without lithiasis (gallstones). **Microcrystalline material and cholesterol crystals** may be present in the bile, usually in association with calculi (Sandmeier and Mihaescu, 2001). Most cases of acute and chronic cholecystitis are nonbacterial and an aspirate of the gallbladder contents reveals a suspension of calcium carbonate and/or cholesterol.

A type of chronic cholecystitis described as **xanthogranulomatous cholecystitis (XGC)** is characterized by a chronically inflamed, thickened gallbladder wall with the presence of many lipid-laden macrophages.

The **association of XGC with carcinoma** of the gallbladder has been repeatedly noted (Goodman and Ishak, 1981; Benbow and Taylor, 1988; Lopez et al, 1991; Krishnani et al, 2000).

Cytology of Xanthogranulomatous Cholecystitis

The cytologic diagnosis of XGC should be considered if a needle aspirate of bile from the gallbladder contains **large foam macrophages with multinucleated giant cells**. Hales and Miller (1987) first reported making this diagnosis by intraoperative fine needle aspirate in a case suspected grossly of carcinoma. Krishnani et al (2000) reported a series of 31 cases of xanthogranulomatous cholecystitis, 11 associated with gallbladder adenocarcinoma.

Krishnani et al described the presence of benign **epithelial cells resembling mesothelial cells** in cohesive clusters as an important morphologic feature of XGC. Other findings, besides the foam cells and **multinucleated giant cells**, were **pink granular background** on May-Grunwald-Giemsa-stained smears. These authors also emphasized the problem with

identification of coexisting carcinoma in some cases in the presence of epithelial atypia caused by XGC.

Carcinoma

Carcinoma of the gallbladder is a rare disease of older patients, accounting for fewer than 0.5% of all cancers in women and less than 0.2% of all cancers in men. The incidence is higher in native Americans and Hispanic Americans and there is a **strong association with gallstones**, which are found in more than 80% of cases. Carcinoma is a clinically unsuspected finding in about 2% of cholecystectomy specimens and is most frequent in patients with cholesterol gallstones. The tumors are mainly **adenocarcinomas** of varying degrees of differentiation, though **mucoepidermoid** and **squamous carcinomas** may occur.

Das et al (1998) reported positive cytology in 48 of 82 cases of gallbladder carcinomas with a variety of clinical diagnoses. Sensitivity as high as 88% has been reported by others in a small series of cases (Akosa et al, 1995; Dodd et al, 1996) while 90% sensitivity was reported in a series of 36 cases by Krishnani et al (2000). In a study of 250 patients in whom cholecystectomy was performed for cholelithiasis or cholecystitis, Alonso de Ruiz et al (1982) found **good correlation between histology and the cytology of aspirated bile from the resected gallbladder** in 4 of 6 cases with carcinoma in situ and 7 of 7 cases with invasive carcinoma. There was **poor correlation with epithelial hyperplasia and dysplasia**.

The features of adenocarcinoma of gallbladder in needle aspiration biopsy have been described by several observers. In the larger series of cases reported by Akosa et al (1995), Das et al (1998), and Krishnani et al (2000), the cytologic features were those of a **classical adenocarcinoma** with loosely structured clusters of cancer cells with irregular large nuclei and very **prominent nucleoli**. Das et al (1998) reported one case of **mucoepidermoid carcinoma**, five cases of **squamous carcinoma** and two cases of **small cell carcinoma**, all with classical features of these cancers as described elsewhere in this book (see Chap. 20).

Benign Tumors

Papillomas, adenomas, adenomyomas and granular cell tumors have been described in the gallbladder, but are very uncommon. In a series of 1605 cholecystectomies, Kozuka et al (1982) reported 79 invasive carcinomas compared with 18 adenomas, of which 7 had carcinoma in situ. To our knowledge, there are no reports of the cytologic diagnosis of gallbladder adenomas.

25

Effusions in the Absence of Cancer

ANATOMY AND HISTOLOGY OF THE PLEURAL, PERITONEAL, AND PERICARDIAL CAVITIES

The organs contained within the body cavities are surrounded by a thin membrane, sometimes referred to as **serous membrane**, or **serosa**. The leaf of the membrane surrounding the organs is known as **the visceral layer**. The visceral layer extends to the outer walls of the body cavity where it forms the **parietal layer**. The visceral and the parietal layers are in **continuity with each other** and thus form a self-contained, closed cavity that is not in contact with the outside world.

The three body cavities (the pleura, peritoneum, and pericardium) have a common embryologic origin in the mesenchymal embryonal layer. The **pleura encloses the lungs; the peritoneum, the intestinal tract; and the pericardium, the heart** (Fig. 25-1). The serous membranes are lined by **the mesothelium** composed of a **single layer of flat cells**, supported by connective tissue, and an appropriate vascular and nervous apparatus (Fig. 25-2). Under favorable circumstances of perfect fixation and gentle processing, a **brush border** may be observed on the luminal surface of the mesothelial cells (Fig. 25-3).

In the absence of disease, **the parietal and the visceral layers of the mesothelium are separated by a thin layer of lubricating fluid** that facilitates the movements of the two membranes against each other. The flow of the lubricating fluid is regulated by mesothelial cells.

Transmission electron microscopy of the mesothelium reveals a continuous single layer of cells bound to each other by desmosomes and gap junctions, with surface microvilli extending toward the body cavity (Policard et al, 1955; Odor, 1956; Felix, 1961; Cotran and Karnovsky, 1968; Efrati and Nir, 1976). **Pinocytotic vesicles** are numerous at both poles of the mesothelial cells (Fig. 25-4). Scanning electron microscopy confirmed that the mesothelial cells lining the surface are provided with **short microvilli** of equal length. The **microvilli of normal mesothelial cells are too small to be visible in light microscopy. The presence of longer, visible microvilli on the surfaces of mesothelial cells usually indicates a disease process**, as will be discussed in Chapter 26.

ACCUMULATION OF FLUIDS (EFFUSIONS) IN BODY CAVITIES

Under pathologic circumstances, **the two leaflets of the serous membrane may be separated from each other** either

P.920

because of the **presence of air or fluids** within the body cavity. The presence of **air**

constitutes, respectively, a **pneumothorax**, a **pneumoperitoneum**, or a **pneumopericardium**.

Figure 25-1 Schematic representation of the three body cavities. The visceral layer of the peritoneum is identical with the serosal lining of the intestinal tract.

From the point of view of diagnostic cytology, the **accumulation of excess fluids** in the body cavities is of capital significance. **The mere presence of a fluid in any of the body cavities indicates a pathologic process.** The presence of **blood** in one of the body cavities, usually caused by **trauma** or **rupture of a viscus**, results in a **hemothorax**, **hemoperitoneum**, or **hemopericardium**. These conditions are irrelevant in the context of this book.

Figure 25-2 Normal mesothelial lining of the pericardium. There is a single layer of flat cells on the surface of supporting connective tissue.

The presence of fluid other than blood constitutes an **effusion**, which in the abdomen is called **ascites**. Although the usual purpose of cytologic investigation in such cases is to determine the presence or absence of tumors cells, many other conditions can also be identified. The fluids or effusions may be classified as **transudates** or **exudates** (Fig. 25-5).

Transudates

The transudates are clear, straw-colored fluids, characterized by a **low specific gravity**, often below 1.010, and **low protein**

P.921

content (usually below 3 g/100 ml). The accumulation of transudates within body cavities is caused by **filtration of blood serum across the physically intact vascular wall** either by **reduced intravascular osmotic pressure**, as in hypoproteinemia, or by **increased filtration pressure**, as in heart failure.

Figure 25-3 Brush border, mesothelial cells (pericardial sac aspiration). (Oil

immersion.)

Figure 25-4 Electron micrograph of a mesothelial cell, rat peritoneum. A cytoplasmic process (CP) with a few microvilli may be noted. Such processes form much of the peritoneal covering. Note the comparatively large nucleus (N). Numerous pinocytotic vesicles (*arrows*) may be noted in the cytoplasm. L, lumen of peritoneal cavity. ($\times 17,000$.)

The **cellular components of transudates** are scanty and are limited to a few mesothelial cells and leukocytes. **When the cytologic components of an effusion are more complex, the effusion is, in all likelihood, an exudate.**

Figure 25-5 Diagrammatic representation of differences between a transudate and an exudate.

Exudates

The exudates result from an accumulation of fluid within the body cavities, **associated with damage to the walls of the capillaries**. The exudates are **cloudy or opaque fluids** of various colors. **The presence of blood-tinged, reddish fluid is an important diagnostic sign that should be recorded because it may indicate the presence of a primary or metastatic tumor or tuberculosis.**

The exudates are characterized by a relatively **high protein content** (usually above 3 g/100 ml) and, therefore, a **high specific gravity** (usually above 1.015). The exudates are **rich in fibrin and may coagulate on standing and usually contain a variable, but often significant, population of cells that are the target of cytologic investigations**. There are several causes of exudates:

- **Inflammatory conditions that are usually, but not always, caused by infectious processes in the organ enclosed by the serous membrane**
- **Tumors that may be primary or metastatic**
- **Miscellaneous causes, discussed below**

Storey et al (1976) stated that **cytologic examination and determination of protein levels** were the most useful methods of assessment of pleural effusions: in the great majority of **cancer patients**, the effusions had **protein levels of 3 g/100 ml or more**. Protein values **below 3 g/100 ml** occurred mainly in **patients with congestive heart failure**, the principal cause of chronic effusions in the absence of cancer.

P.922

A very rare form of abdominal effusion is **chylous effusion** caused by a **rupture or obstruction of thoracic duct** that carries **whitish liquid lymph** from abdominal lymph nodes to the heart.

METHODS OF INVESTIGATION OF EFFUSIONS

The customary methods of investigation of effusions are **cytologic examination** of the fluid and a **biopsy** of the pleura, pericardium, or peritoneum, sometimes supplemented by **immunocytologic, biochemical, bacteriologic or cytogenetic** investigation. Light (2002) discussed in detail the clinical and biochemical indications for thoracentesis and cytologic examination of pleural effusions.

The technical details of processing fluid samples are discussed in Chapter 44. The cytologic examination is usually performed on **smears** of centrifuged sediment that may be prepared by manual methods or by some of the newer methods of processing of liquid samples. The smears may be either **fixed immediately and stained by the Papanicolaou method** or, as some observers prefer, **air-dried, fixed in methanol, and stained** by using one of the modifications of the **May-Grünwald-Giemsa (MGG) stain**.

It is **strongly advised to process the remainder of the specimen as a cell block** which

can provide structural information and can be used for special stains or immunostaining. In a recent extensive review of the subject of immunocytochemistry in effusions, Gong et al (2003) noted that samples processed by the ThinPrep (Cytoc Corporation, Boxborough, MA) method were equivalent to cell blocks, except for markers of nuclear proliferation. Thus, in our judgment, there is no reason to abandon **cell blocks** as the **least expensive** and **satisfactory target for ancillary studies**.

A number of biochemical methods has been used in the evaluation of effusions. Thus, the level of **lactic dehydrogenase** and other **enzymes**, several **antigens** such as human chorionic gonadotrophin (hCG), carcinoembryonic antigen (CEA), and CA-125 may be measured. The value of these procedures in diagnosis or in monitoring the effects of treatment is being debated. They sometimes supplement, but never replace, the cytologic examination.

Many **immunocytologic procedures** may serve to **identify and classify cancer cells** in effusions (Coleman and Ormerod, 1984; Johnston, 1987; Bedrossian, 1994). The technical aspects of these procedures are discussed in Chapter 45. The **subtyping of lymphocytes** in effusions, either by immunochemistry or flow cytometry, is sometimes helpful in the assessment of lymphocyte populations in various conditions but is indispensable in subclassification of malignant lymphomas (see Chaps. 26 and 31 for further discussion).

Cytogenetic analysis of cells in fluids may yield important data on the nature of the effusion, particularly in difficult diagnostic situations. There are **two modes of cytogenetic analysis**. The older method calls for examination and analysis of chromosomes in **metaphases in cultured cells**. Newer approaches utilize **specific DNA probes** to chromosomes, individual genes or targeted translocations by fluorescent in situ hybridization (**FISH**) method, applied to interphase nuclei.

DNA ploidy analysis and molecular analysis of tumor cells by methods such as Southern blotting (discussed in Chap. 3) may also be applied to select populations of cells in effusions. The value of these procedures and of tissue biopsies in the diagnosis of effusions is discussed in this chapter and in Chapter 26.

CELL POPULATIONS IN BENIGN EFFUSIONS

Effusions as a Tissue Culture Medium

The body fluids constitute an **ideal natural tissue culture medium** wherein desquamated cells, benign and malignant, may proliferate freely. The temperature, supply of nutrients, oxygen and carbon dioxide are provided by the body of the patient and regulated by much finer homeostatic mechanisms than is possible in vitro. The morphology of cells growing in tissue culture is often different from the cells of origin. This accounts for some of the problems of morphologic cell identification and diagnosis. Specifically, **in actively growing tissue cultures, the differentiation of benign from malignant cells may prove to be difficult**. Effusions also offer the benefit of study of cells and their interrelationships in a natural setting. Many of the established **human cancer cell lines** used for in vitro studies are **derived from effusions**, rather than from solid tissues. Apparently, the ability of these cells to proliferate in the effusion enhances the chances of successful growth in vitro. Thus, the study of effusions constitutes a precious scientific resource that has not been fully explored as yet.

Principal Families of Benign Cells

The principal cell types encountered in the absence of cancer are: **mesothelial cells**,

macrophages (histiocytes), blood cells, and miscellaneous other cells. These are described in the following pages.

Mesothelial Cells

Histology

An effusion within the body cavities brings about separation of the two mesothelial layers. As a consequence, the flat mesothelial lining cells **become cuboidal in shape**. In the presence of an **inflammatory process, and sometimes under other circumstances**, the orderly arrangement of the mesothelial cells is disturbed. **There may be extensive proliferation of mesothelium, both in thickness and in depth, with the formation of several layers of mesothelial cells, sinuses, and channels in continuity with the surface** (Fig. 25-6).

P.923

Figure 25-6 Proliferation of mesothelium in pleurisy. *A.* Numerous channels lined by mesothelial cells. *B.* Focal surface proliferation of mesothelial cells.

Cytology

Aspirates and Scrapes.

When **mesothelial cells** are **scraped or aspirated by a needle** from the surface of the pleural or abdominal cavity, they appear as **sheets of polygonal cells, about 20 μ m in diameter, that are usually separated from each other by clear gaps or “windows.”** The cells have a **delicate, yet sharply demarcated, cyanophilic or eosinophilic cytoplasm and round or oval nuclei.** The nuclei, generally located in the center of the cell, are of **even size, sharply demarcated, slightly granular, and contain one or two, centrally located, readily visible nucleoli** (Fig. 25-7A,B). The presence of nucleoli corresponds to the

P.924

active metabolic status of these cells that normally produce and maintain the level of fluid lubricating the surfaces of the opposing mesothelial layers. Occasionally, a **central fold (crease)** may appear in the nucleus (Fig. 25-7C).

Figure 25-7 Benign mesothelial cells in sheets or clusters. *A.* A sheet of mesothelial cells obtained during lung aspiration in a 64-year-old female. Note the gaps or “windows” among the cells. *B.* A sheet of mesothelial cells observed in an aspirate of the liver. Note the gaps or “windows” between cells. *C.* Direct scraping of pleural surface showing a sheet of mesothelial cells. Note nuclear folds or creases—a feature of unknown significance. *D.* Linear fragment of mesothelium observed in a cell block of pericardial fluid.

The origin of these cells from the mesothelial surface is best documented in cell blocks that show the linear nature of the clusters cut “on edge” (Fig. 25-7D).

Effusions.

In effusions, the **mesothelial cells** desquamate from the surface of the lining of the body cavity and accumulate or even proliferate in the body fluids. **Free-floating mesothelial cells** in fluids appear singly, in doublets, or in clusters of variable sizes and configuration.

Single mesothelial cells in body fluids are usually **spherical or oval** and measure between 15 and 20 μm in diameter. The **cyanophilic or faintly eosinophilic cytoplasm** is sharply demarcated (Fig. 25-8A). Under higher magnification, **two cytoplasmic zones** can be recognized: **a perinuclear, denser zone, and a peripheral, clear zone** (Fig. 25-8B). The difference is caused by an accumulation of cell organelles in the perinuclear area. A characteristic feature of mesothelial cells in doublets or small linear clusters is the **flattening of the opposite cell membranes with formation of a clear gap or “window”** (Fig. 25-8B,C). The “windows” are most likely due to microvilli separating the cells. Indeed, Spriggs and Meek (1961) pointed out that free-floating mesothelial cells in effusions may show a **narrow brush border** that is best observed in air-dried, MGG-stained smears but may also be found in fixed smears and in electron microscopic preparations (see Fig. 25-3). In light microscopy, under high magnification, the **mesothelial cells often show a very narrow clear zone surrounding the cell membrane**, probably corresponding to the brush border, which is better visualized in air-dried smears. From time to time, mesothelial cells contain **eosinophilic cytoplasmic inclusions**, identical to those observed in urinary sediment and described in Chapter 22. Cell-in-cell arrangement of mesothelial cells may occur, although this is usually observed in cirrhosis

of the liver (see below).

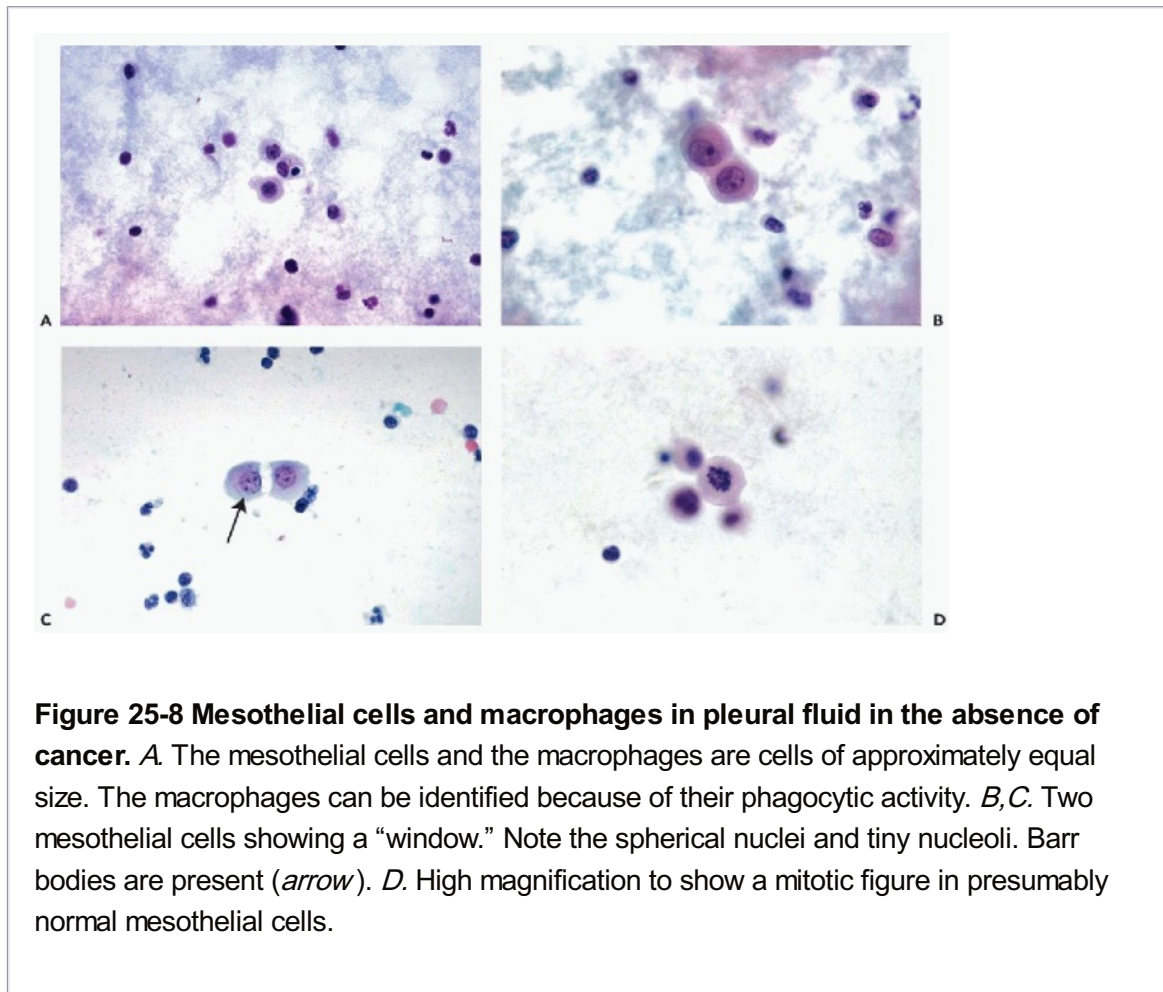

Figure 25-8 Mesothelial cells and macrophages in pleural fluid in the absence of cancer. A. The mesothelial cells and the macrophages are cells of approximately equal size. The macrophages can be identified because of their phagocytic activity. B,C. Two mesothelial cells showing a “window.” Note the spherical nuclei and tiny nucleoli. Barr bodies are present (*arrow*). D. High magnification to show a mitotic figure in presumably normal mesothelial cells.

The **nuclei** of free-floating mesothelial cells are relatively large and occupy about **half of the cell diameter**. The nucleus is usually **centrally located** within the cell. The morphologic characteristics of the nucleus are of great diagnostic importance. The **nuclear membrane is prominent**. The **chromatin net is delicate and rather inconspicuous**, with a few small, but sharply defined, chromocenters and occasionally one or two **tiny nucleoli**. **Prominent nucleoli, which are a landmark in mesothelial cells in aspirated**

P.925

samples, are rarely seen in free-floating, desquamated mesothelial cells. In female patients, a single **Barr body** (sex chromatin body) may be observed (Fig. 25-8B,C).

Mesothelial Cell Clusters.

Freely growing mesothelial cells in effusions may also form clusters of various configurations, composed of a variable number of cells (Fig. 25-9). Some of the clusters may be circular, linear, or have a rosette-like configuration (Fig. 25-9A). In single layer clusters, the “windows” separating the mesothelial cells from each other are readily observed. The clusters are readily recognized as benign, so long as the regular configuration of the component cells and their nuclei can be visualized. The outer edges of such clusters are usually composed of rows of cells showing smooth borders or “scalloping.” However, the identification of the clusters as mesothelial in origin becomes much more difficult if the clusters are multilayered, of spherical “papillary” configuration, or poorly fixed with resulting nuclear hyperchromasia (Fig. 25-9B-D). Particularly disturbing are **very large spherical clusters** that are, from time to time, observed

in chronic effusions, particularly in the pericardium (Fig. 25-9C). Spriggs and Jerome (1979) reported such a case and observed the presence of a central core of collagen. **Recognizing such clusters as benign is very difficult** because malignant tumors, particularly mesotheliomas, may form very similar clusters (see Chap. 26). The dilemma is usually solved by searching for additional clues in single cells that are almost always available in a cytologic preparation. In the absence of clear-cut malignant cells or pertinent clinical history, it is wise to report the papillary clusters with caution.

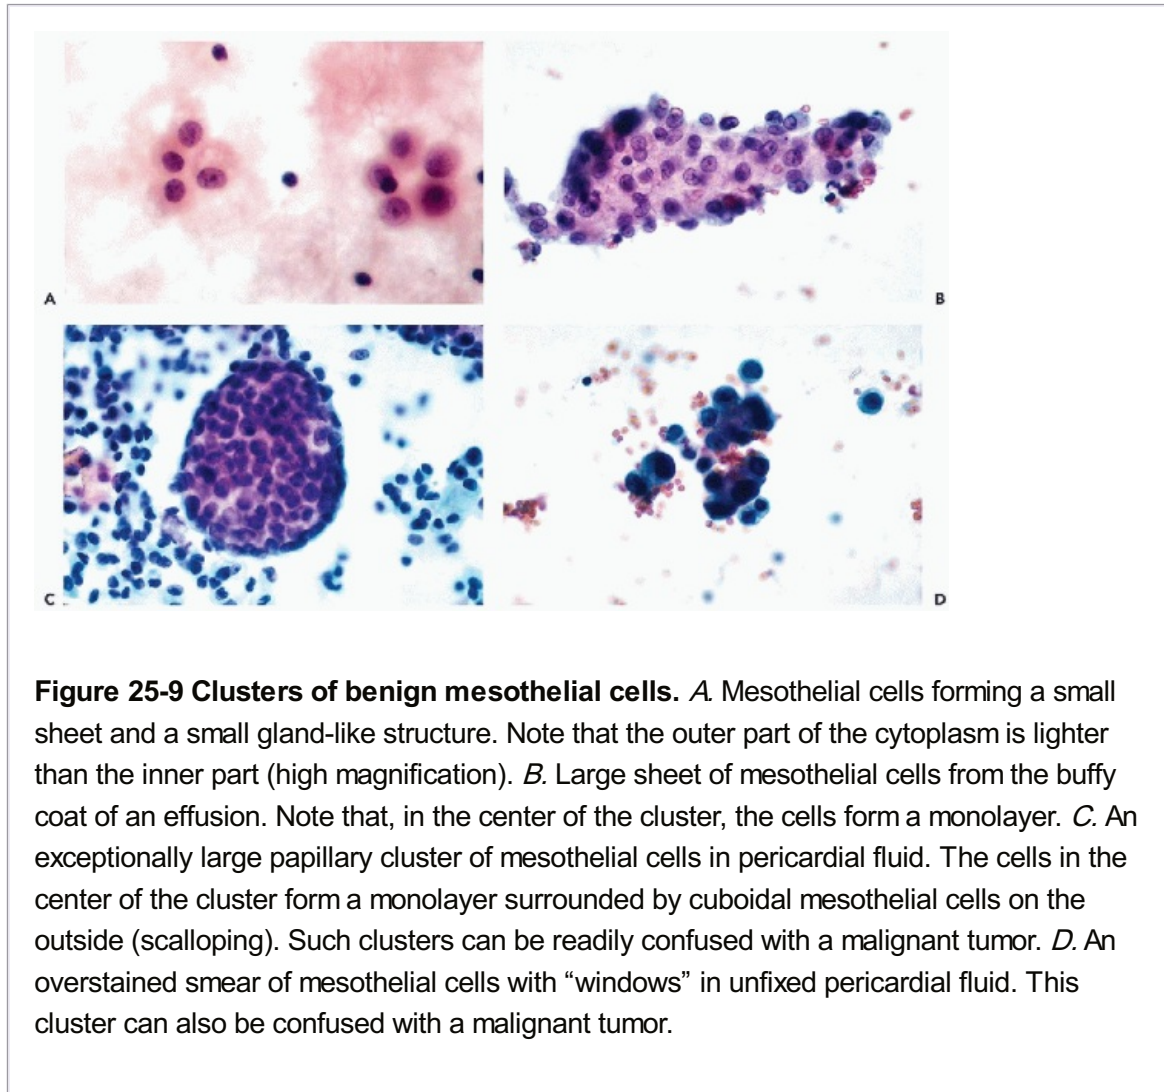

Figure 25-9 Clusters of benign mesothelial cells. *A.* Mesothelial cells forming a small sheet and a small gland-like structure. Note that the outer part of the cytoplasm is lighter than the inner part (high magnification). *B.* Large sheet of mesothelial cells from the buffy coat of an effusion. Note that, in the center of the cluster, the cells form a monolayer. *C.* An exceptionally large papillary cluster of mesothelial cells in pericardial fluid. The cells in the center of the cluster form a monolayer surrounded by cuboidal mesothelial cells on the outside (scalloping). Such clusters can be readily confused with a malignant tumor. *D.* An overstained smear of mesothelial cells with "windows" in unfixed pericardial fluid. This cluster can also be confused with a malignant tumor.

Diagnostic problems may also occur if the effusion is not processed rapidly. **Processing delays** may cause the nuclei to **stain intensely with hematoxylin** (Fig. 25-9D) rendering their interpretation very difficult. In these situations, the similarity of nuclear sizes (and absence of clearly abnormal cells) are in favor of a benign process.

Mitoses in Benign Effusions.

There is no doubt that normal mitotic figures can be observed in benign mesothelial cells growing in effusions (see Fig. 25-8D). Still, **mitotic activity in fluids calls for a very careful review of the material** to rule out a primary or metastatic malignant tumor. As will be set forth in Chapter 26, in some cases, the inconspicuous tumor cells may resemble mesothelial cells.

The presence of **abnormal mitoses** has been reported in a very small number of patients in

the absence of cancer (Papanicolaou, 1954; Melamed, 1963). Because **abnormal mitoses must be considered as a landmark of cancer**, it is inevitable that in such extremely rare cases, an erroneous diagnosis will be rendered.

Special Stains in Identification of Mesothelial Cells

Conventional Stains

The **differentiation of mesothelial cells from morphologically similar cancer cells** has been the subject of inquiry for many years. In 1959, Nathan Chandler Foot examined the specificity of the **periodic acid-Schiff reagent (PAS)** for the mesothelial cell. He found that the cytoplasm of most **mesothelial cells contained PAS-positive granules** concentrated at the periphery and representing, in all likelihood, neutral mucopolysaccharides. Although the cytoplasm of some **cancer cells** stained with PAS, the red **color was diffuse** and not confined to the granules. Mavrommatis (1964) generally confirmed the observations of Foot. However, Pfitzer (1966) denied any diagnostic value in the use of PAS technique. In my experience, the PAS method is rarely of diagnostic assistance in a critical morphologic situation.

Of greater use are **stains identifying mucin, such as mucicarmine. Mucicarmine-positive staining has never been observed in this laboratory in mesothelial cells** whereas it is an excellent indicator of mucin-producing carcinomas.

Antibodies

Many attempts have been made to identify cancer cells in effusions with monoclonal antibodies. A monoclonal antibody recognizing mesothelial cells, developed by Singh, was used by us in the identification of a mesothelioma of the tunica vaginalis of the testis (Japko et al, 1982) but there is no evidence that this antibody became commercially available. Davidson et al (2001) observed that **antibodies to desmin** mark the mesothelial cells more intensely than cancer cells. Panels of antibodies used in the differential diagnosis of mesotheliomas from benign mesothelial cells or other tumors are discussed in Chapter 26 and Chapter 45.

Macrophages (Histiocytes)

The **macrophages are of bone marrow origin and represent transformed monocytes**. The proof of this origin is discussed in Chapter 19. In the past, it had been thought that the presence of macrophages in effusions reflected a chronic inflammatory process. Current evidence strongly suggests that macrophages are **ubiquitous cells** that can also be observed in the presence of cancer and under other circumstances as well. Using immunocytochemistry and flow cytometry with the marker CD14 to identify monocyte/macrophage cell populations in benign and malignant effusions, Risberg et al (2001) confirmed that these cells are present in virtually all effusions and often comprise a surprisingly high proportion of all cells, up to 85%. The presence of macrophages was somewhat higher in female than male patients but was unrelated to the presence or absence of cancer. The relationship of macrophages to cancer cells is discussed in Chapter 26.

Studies based on scanning and transmission electron microscopy of fluids disclosed that **many cells that have been hitherto classified as of mesothelial origin, particularly cells with large cytoplasmic vacuoles, belong to the family of macrophages** (Domagala and Woyke, 1975; Murad, 1973; Domagala and Koss, 1977). The **surface configuration** of the two cell types in scanning electron microscopy discloses major differences. The **mesothelial cells** are characterized by the presence of **regular short microvilli or a mixture of microvilli with**

bleb-like surface structures, the latter characterizing older cells. The **macrophages** have a very characteristic surface configuration, wherein the **cell membrane forms folds or ridges** (Fig. 25-10). Although mesothelial cells contain some lysosomes (Cotran and Karnovsky, 1968), they do not possess the elaborate lysosomal apparatus characterizing the macrophages.

In effusions, the **number** of macrophages is extremely variable, depending on the condition of the patient. In some infectious effusions, notably in *Legionella micdadei* infection, the macrophages **may be the dominant cell population**.

The macrophages are **usually seen as mono- or binucleated cells similar in size to mesothelial cells** (15 to 20 μm in diameter). These cells usually occur **singly or in loosely arranged groups** and **do not show cytoplasmic molding or "windows."** The macrophages are characterized by **foamy cytoplasm**, studded with minute vacuoles, or containing phagocytized particles, and a **cell border that readily blends with the smear background, in contrast with the sharply demarcated mesothelial cells** (see Fig. 25-8A; Fig. 25-11A). The cytoplasm of the **macrophages may become markedly distended with large, clear vacuoles** (Fig. 25-11B).

The **position of the nuclei of mono- or binucleated macrophages** is variable. In most macrophages, the nuclei are **located in the peripheral portion of the cell** and sometimes stain somewhat denser than the nuclei of mesothelial cells in the same field. **Kidney-shaped, indented nuclei with finely granular chromatin, and sometimes tiny nucleoli, are common in macrophages and uncommon in mesothelial cells.** In vacuolated macrophages, **the nuclei are often compressed and pushed to the periphery** (Fig. 25-11C). However, the nuclear configuration or staining properties are of limited value in separating macrophages from mesothelial cells.

Large multinucleated macrophages, either foreign body giant cells or Langhans' type cells, may occasionally be observed. Such cells are usually observed in fluids as a **reaction to foreign material after a surgical intervention**, in **granulomatous inflammations**, or after **radiotherapy**, presumably as a reaction to necrosis of cells (Fig. 25-11D). Ordoñez et al (1998) reported that the so-called **nodular mesothelial hyperplasia is composed of macrophages** (see Chap. 26). **Clusters of macrophages** were described by Choi and Song (2001) in pleural fluid in a case of this rare disorder.

Phagocytic activity and lysosomal activity are characteristic functions of macrophages. These features may be used to good advantage in the identification of these cells in light microscopy (see Fig. 25-8A; Fig. 25-11A). **Pigments, organic or inorganic particle or cell engulfment by macrophages,** may be observed (see below).

Figure 25-10 Pleural fluid. Scanning electron microscopy of two cells of approximately equal size (10 μm in diameter) and similar light microscopic configuration. Cell (A) shows a surface arrangement of folds and ridges, identifying it as a macrophage. Cell (B) shows short microvilli and blebs on its surface, identifying it as a mesothelial cell. (A: $\times 5,500$; B: $\times 4,600$.) (Courtesy of Dr. W. Domagala.)

Figure 25-11 Various forms of macrophages in effusions. A. A cluster of macrophages recognized because of phagocytosis of an unknown substance. Note the peripheral position of nuclei of these cells. B. Pure population of macrophages in pleural fluid of an 83-year-old woman with pneumonia. C. A vacuolated macrophage under high magnification showing the signet ring appearance of these cells with small nuclei. D. Macrophages forming multinucleated giant cells in ascitic fluid following a surgical intervention.

lysosomal activity in macrophages. None of these functions is normally observed in mesothelial cells but there are **rare exceptions, when mesothelial cells acquire phagocytic properties.** In such cases, the distinction between macrophages and mesothelial cells is impossible in light microscopy. **In unfixed smears from fresh effusion,** the macrophages may be identified by **supravital staining** with neutral red or Janus green which is absorbed by macrophages (and some leukocytes) but not by mesothelial cells (Foot and Holmquist, 1958). Identification of macrophages in effusions with the specific cell surface marker **CD14** was reported by Risberg et al (2001).

Blood Cells

Erythrocytes

The presence of **intact red blood cells** in body fluids is usually caused by a **traumatic tap.** In **hemorrhagic effusions, fresh and degenerated erythrocytes** are usually seen against a background of **fibrin.** **Sickle cell anemia** may be identified in fluids **in the form of sickle-shaped erythrocytes** (Dekker et al, 1975).

Erythrophagocytosis

Ingestion of the patient's own erythrocytes by macrophages in pleural or ascitic fluids may be occasionally observed, for example, in **dialysis ascites** (see below). Several other examples have been observed by us under a variety of circumstances (Fig. 25-12A; see Fig. 25-22A). It is not known whether the erythrocyte surface has to be modified for these cells to be phagocytosed. Erythrophagocytosis has been observed in a rare disorder defect of lysosomes occurring in macrophages, known as the **Chediak-Higashi syndrome** (Valenzuela et al, 1976) and may be observed **in some forms of malignant lymphoma** (see Chap. 26). Zaharopoulos (2001) observed erythrophagocytosis in pleural fluid from a patient with **autoimmune hemolytic anemia**, induced by Epstein-Barr virus.

Leukocytes

Lymphocytes.

Leukocytes in effusions are extremely common. In **chronic effusions** of long-standing, **lymphocytes may be the dominant** population of leukocytes (Fig. 25-12B). If the lymphocytes are **numerous** and, especially if no other leukocytes are present, the possibility of a **chylous effusion** caused by a rupture of the thoracic duct, **tuberculosis, chronic lymphocytic leukemia, or well-differentiated malignant lymphoma should be investigated.** **Typing and enumeration of B and T lymphocytes and their subtypes may be of diagnostic value.** The implications of this observation in reference to cancer in effusions is discussed in Chapter 26.

Granulocytes.

Polymorphonuclear neutrophilic leukocytes (polys) invariably indicate an **inflammatory process**, which may be secondary to infection, cancer or other disorders. **Eosinophilic leukocytes** may be seen in **eosinophilic pleural effusions** (see below) and in a variety of inflammatory processes. They are not **uncommon in tuberculosis** and are **rarely seen in Hodgkin's disease.**

Plasma Cells.

Plasma cells may be noted in **chronic inflammatory processes in multiple myeloma** and in **Hodgkin's disease** (see Chap. 26).

Megakaryocytes

Calle (1968) was the first to observe these cells in the abdominal fluid of a female patient with **myeloid metaplasia**. **Extramedullary hematopoiesis** appears to be the common denominator of cases reported by others (Vilaseca et al, 1981; Pedio et al, 1985; Silverman, 1985). Barziotas and Naylor (1986) observed megakaryocytes in a bloody pleural effusion in a **patient with overdose of an anticoagulant** (Fig. 25-12C).

Abnormal megakaryocytes may signal a serious hematopoietic disorder (see Chap. 26).

Other Hematopoietic Cells

Busmanis et al (1998) reported the presence of a **broad spectrum of hematopoietic cells, mimicking leukemia**, in the pleural fluid in a patient receiving **granulocyte-stimulating factor** after chemotherapy.

Other Benign Cells Encountered in Effusions***Anitschkow's Cells***

Cells similar to **Anitschkow's myocytes**, that have a very characteristic **central bar of chromatin, from which radiate numerous short lateral processes (caterpillar nuclei)**, have been noted in a rare case of effusion of long standing and of unknown etiology (see Fig. 25-7C). Molina and Schnadig (2001) observed such cells in six of fourteen pericardial scrapings and concluded that these are **modified mesothelial cells**. Similar cells may be observed in oral and conjunctival squamous cells (see Chaps. 21 and 41).

Liver Cells

Liver cells, singly or in sheets, may be observed if this organ is penetrated accidentally while fluids are aspirated from the **right pleural cavity** (Fig. 25-12D,E). The identification is quite easy because of the **large size of the cells and their abundant, faintly vacuolated cytoplasm surrounding large single or double nuclei**. The identity of the cells may be confirmed in cell blocks. Tiny, green-staining **intracytoplasmic bile deposits** may be observed in fresh preparations. In older preparations, the bile forms green or yellow amorphous masses.

Cells Derived From the Respiratory Tract

Readily recognizable **ciliated bronchial cells** and **dust-containing macrophages in pleural fluid** are the result of **injury to lung tissue during tapping**, and may suggest a **bronchopleural fistula** or, exceptionally, a **mediastinal teratoma** with elements of the respiratory tract.

Figure 25-12 Erythrophagocytosis, benign lymphocytes, megakaryocytes, and liver cells. *A.* Erythrophagocytosis. High magnification to show phagocytosed red blood cells within the cytoplasm of macrophages. *B.* A large population of benign lymphocytes in pleural fluid in a case of pulmonary tuberculosis. *C.* Two megakaryocytes in pleural fluid. The lobulated nuclei are clearly shown. *D,E.* Hepatocytes obtained during aspiration of pleural fluid from the right pleural cavity (smear and cell block). The liver cells were aspirated inadvertently across the diaphragm.

Squamous Cells

Benign squamous cells derived from the epidermis of the **skin** are very rarely seen in effusions. In general, the **presence of squamous cells in effusions, regardless of their morphology**, suggests a **squamous carcinoma** (see Chap. 26). In a case described by Cobb et al (1985), benign squamous cells, anucleated squames, and hair shafts were observed in pleural fluid from a boy with **ruptured benign cystic teratoma (dermoid cyst) of the anterior mediastinum**.

Fat Cells and Striated Muscle

These cells, originating in subcutaneous fat and muscle, may be noted occasionally. They are incidental to tapping.

Pigments

Hemosiderin

Cytoplasmic hemosiderin deposits in the form of **fine granular golden-brown pigment** are found in macrophages in effusions in **chronic hemorrhagic pleurisy or pericardial effusion**. The large hemosiderin deposits may obscure the nuclei of macrophages and **may mimic melanin accumulation** and lead to a mistaken diagnosis of a malignant melanoma. Hemosiderin stains **green with iron stains** which can be used for identification of this pigment (see Chap. 19).

Melanin

Melanin may be observed in macrophages as a **diffuse or finely granular brown cytoplasmic stain in the presence**

P.930

of metastatic malignant melanoma. Allen et al (1997) observed **melanin accumulation in macrophages in a pleural effusion in a patient with melanosis coli**, a benign condition in which melanin accumulates in the epithelial cells of the colon. Melanin can be identified with a number of monoclonal antibodies such as HMB45 and MART-1 (Beaty et al, 1997) (see also Chap. 26).

Bile Pigment

This pigment, recognized by its natural green color, can be observed in the cytoplasm of macrophages in the presence of metastatic, **bile-producing hepatocellular carcinoma**. Bile in ascitic fluid in a case of **gall bladder rupture** was reported by Argyres et al (1998).

Crystals and Other Inorganic Components

Charcot-Leyden Crystals

These **spindle-shaped crystals** are **derived from eosinophils and may occur in eosinophilic pleural effusions** (Fig. 25-13A). Krishnan et al (1983) observed Charcot-Leyden crystals in pleural fluid rich in eosinophils in a young patient with a **benign cystic teratoma**. Naylor and Novak (1985) observed the crystals in eight patients with eosinophilic pleural effusion, two of which were "idiopathic" and six associated with other disorders (for description of eosinophilic pleural effusion, see below).

Figure 25-13 Crystals and other inorganic structures in effusions. *A.* Spindle-shaped Charcot's crystals (*arrows*) in a case of eosinophilic pleural effusion. *B.* Hematoidin crystals (oil immersion). *C,D.* Liesegang's rings in ascitic fluid in a patient with breast cancer. Note the striated outer ring surrounding a homogeneous center. (*B:* Photo courtesy of Dr. Zacharopoulos, Galveston, TX.)

Hemoglobin and Hematoidin Crystals

Both types of crystals may occur in hemorrhagic fluids of long standing, derived from various sources, including bloody effusions. Hemoglobin crystals, resulting from polymerization of hemoglobin, **phagocytized by polymorphonuclear leukocytes** in pleural and cerebrospinal fluid, were reported by Zacharopoulos and Wong (1997). These crystals are small and vary in shape and size. Hematoidin crystals are much larger and represent a stage of bile formation from hemoglobin. Again, they may be of various shapes, most in the form of freefloating spherical cockleburs filled with crystals or filaments (Fig. 25-13B) (Zacharopoulos et al, 1985).

Immunoglobulin Crystals

Martin et al (1987) observed **spindle-shaped crystalline inclusions in macrophages and extracellular crystals** in ascitic fluid from a patient with cryoglobulinemia. The authors postulated that the crystals (confirmed by electron microscopy) represented **crystallized immunoglobulin** in a patient with plasma cell dyscrasia.

Cholesterol Crystals

These characteristic flat crystals with broken edges may be observed in **chronic effusions of long duration**. Naylor (1990B) reported such crystals in effusions in rheumatoid arthritis.

P.931

Oxalate Crystals

Such crystals were observed in pleural fluid by Reyes et al (1979) in a case of aspergillosis. It has since been documented that the **presence of these crystals**, described in detail in Chapter 19, **is diagnostic of aspergillosis**.

Lamellar Inclusions

Zacharopoulos and colleagues (1998) reported the presence of **membranous lamellar inclusions** of unknown derivation or significance, rendering the macrophages similar to Gaucher's cells.

Liesegang's Rings

Liesegang's rings are approximately **spherical eosinophilic structures** with an **amorphous core** and a well-defined **striated outer ring** (Fig. 25-13C,D). The structures represent most likely a precipitate of a supersaturated solution (Hedges, 1932; Raso et al, 1998). The rings have been observed in various cyst fluids, mainly from the kidney and breast (Sneige et al, 1988; Katz and Ehya, 1990; Raso et al, 1998; Pavot et al, 2001). In renal samples, they may resemble a giant kidney worm, *Dioctophyma renale* (Tuur et al, 1987). We observed these structures in ascitic fluid.

Curschmann's Spirals

Curschmann's spirals are commonly observed in sputum as protein casts derived from bronchioles (see Chapter 19). Similar structures have now been observed in effusions. Wahl (1986) observed these structures in nine peritoneal washings, two pleural fluids, and in a peritoneal dialysis fluid. Wahl hypothesized that the spirals were possibly of connective tissue origin. Dr. Bernard Naylor (personal communication, 1989) confirmed Wahl's observation in three pleural and two peritoneal fluids. In two of the cases, Curschmann's spirals were associated with mucus-producing adenocarcinoma, in one patient with pseudomyxoma peritonei, and in two patients with inflammation. The **spirals are very similar to those seen in the respiratory tract** (see Chap. 19), except for their smaller size (Fig. 25-14). Naylor (1990A) suggested that some of the spirals could be the **product of mucus-producing cancer cells** and, in inflammatory processes, be derived from **connective tissue mucins**.

Figure 25-14 Curschmann's spiral in pleural fluid. (From Naylor B. Curschmann's spirals in peritoneal effusions. *Acta Cytol* 34: 474-478, 1990.)

“Collagen Balls”

These small hyaline structures, surrounded by mesothelial cells, are much more common in pelvic washings than in effusions (Wojcik and Naylor, 1992). For description and illustration of these structures, see Chapter 16.

GENERAL GUIDELINES IN THE INTERPRETATION OF EFFUSIONS

Clinical Data and Techniques of Preparation

The **clinical history** is of paramount importance in evaluating fluid specimens of a difficult nature. **If the clinical data do not support it, the diagnosis of cancer should be made only on secure, irrefutable evidence.** A patient with an erroneous diagnosis of metastatic carcinoma to a body cavity may be deprived of effective treatment for a treatable disease. Most diagnostic errors are made on technically inadequate material, such as thick, overstained

smears, poorly prepared and stained filter preparations, and inadequate evidence in cell blocks. It must be pointed out that the packaging of centrifuged material in paraffin for cell block preparation may create artifacts, such as clustering of cells, which may be misleading. In general, **well-fixed and well-prepared material** that is not subjected to excessive handling in the laboratory **is easier to interpret** and lends itself less to an erroneous diagnosis.

Effusions of Long Standing

Regardless of cause, effusions of long standing are often characterized by an accumulation of **poorly preserved mesothelial cells and macrophages** that cannot always be accurately identified and may be numerous. This is particularly important in the **first tap, which may yield large, blown-up mesothelial cells with enlarged, hyperchromatic nuclei** (see Fig. 25-9D). It is likely that such mesothelial cells are old or dead, and that their enlargement is due to the loss of selective permeability of the cellular membrane. Occasionally, the diagnostic dilemmas are solved on the **second tap**, which will display the morphology of the cells in fluids to a better advantage.

Fluids With Inflammatory Reaction

As a rule of thumb, **the association of cancer cells with a severe inflammatory reaction in an effusion is uncommon**; this usually indicates the presence of an inflammatory process or, in extreme cases, a perforation of a viscous by a malignant process that results in a critical clinical situation. On the other hand, **inflammatory processes such as tuberculosis may persist for a considerable time**. In such fluids, **abnormalities of mesothelial cells are common** (see below). **Thus, in the presence of massive evidence of an**

P.932

inflammatory process, it is advisable to interpret the material with caution.

Avoidance of Errors

General diagnostic **guidelines that help to avoid diagnostic mistakes, and especially the erroneous diagnosis of cancer**, can be summarized as follows:

- **An accurate clinical history must be obtained.**
- **Protein determination should be performed.** If the protein is less than 3 g/100 ml, the presence of cancer is much less likely than if protein is above 3 g/100 ml.

Cytologic diagnosis of cancer should be avoided if:

- **The morphology of cells is not optimal.**
- **The cells and nuclear sizes are monotonous and within upper limits of normal (25 µm in diameter for cells and 10 µm for nuclei), and the nucleocytoplasmic ratio is within normal limits.**
- **There are no structural nuclear abnormalities.**
- **There is evidence of an acute or chronic inflammatory process.**

SPECIFIC NONMALIGNANT DISEASES ASSOCIATED WITH EFFUSIONS

General and Circulatory Disorders

Hypoproteinemia

Low protein levels in the blood may cause **accumulation of fluids in all three body cavities and generalized edema (anasarca)**. The causes are various and comprise inadequate nutrition and various renal diseases. Fluids that may occasionally be submitted for cytologic examination are classic **transudates**, with a low protein level and low cell content that are not likely to cause any diagnostic dilemmas.

Congestive Heart Failure

Congestive heart failure is perhaps **the most common cause of chronic pleural effusion not caused by cancer**. An accumulation of pericardial and ascitic fluid may also occur. Although it is frequently stated that the right pleural cavity is more commonly affected, in my experience, the distribution of effusions is about equilateral. The fluids often are **classic transudates** with a low protein content and scant cellularity that rarely cause any particular diagnostic dilemma.

In heart failure associated with inflammatory changes, such as observed in **rheumatic heart disease or secondary pneumonia**, the effusions contain numerous polymorphonuclear leukocytes, **poorly preserved macrophages and mesothelial cells** in sheets or clusters. The reader is referred to the general discussion above for the guidelines in the diagnostic interpretation of this type of material.

Pulmonary Infarcts

Embolization of pulmonary arteries need not necessarily be associated with pulmonary infarcts if lung function is otherwise normal. Acute infarction does not usually result in an immediate effusion but, as the **infarct becomes organized**, a **marked pleural reaction** may result in a **chronic pleural effusion**, which may be tapped for relief of the patient or for diagnostic study. It is evident from Figure 25-15 that in such fluids, **proliferation of mesothelial cells may be exuberant** and may cause major diagnostic problems if large sheets and clusters of mesothelial cells are present (see Fig. 25-9).

Infectious Processes

Acute Inflammatory Processes

Acute **pneumonia, lung abscess, acute pleurisy, pericarditis, peritonitis, and postsurgical states** are frequently associated with accumulation of fluid in one or more of the body cavities. Such fluids rarely present a diagnostic dilemma because they are composed of **purulent exudate, containing numerous polymorphonuclear leukocytes and necrotic material**. As has been mentioned above, it is not prudent to make a diagnosis of cancer under these circumstances except in the presence of overwhelming evidence.

Legionnaires' Disease

In this disorder, the cell content of pleural effusions is dominated by macrophages that may contain the causative organism *Legionella micdadei* (see below).

Viral Pneumonias

Pleural effusions complicating viral pneumonias usually contain a mixture of lymphocytes and macrophages.

Chronic Inflammatory Processes

Chronic pneumonia, pericarditis, and peritonitis of various causes may also result in accumulation of fluid in body cavities. The cytologic interpretation of this material may lead to some of the principal diagnostic difficulties outlined above. The classic example of such difficulties is **tuberculosis**.

Figure 25-15 Proliferation of mesothelium in pulmonary infarct. Note the multiple layers of mesothelial cells and some nuclear atypia. (H&E.)

P.933

Tuberculosis

Pleural effusions in pulmonary tuberculosis, wherein the **pleura is not directly involved**, are characterized by **predominance of lymphocytes**, an observation confirmed by logistic regression analysis by Ellison et al (1998) (see Fig. 25-12B). Few macrophages or mesothelial cells are present. The **differential diagnosis comprises leukemias and malignant lymphomas** (see Chap. 26), **viral pneumonia**, and very rarely traumatic **chylous effusion**.

Direct involvement of the body cavities by the tuberculous process (tuberculous pleurisy, pericarditis, and peritonitis) may result in a major diagnostic dilemma because of a **marked proliferation of mesothelial cells in sheets and clusters**, many of which may assume **spherical (papillary) configuration, features commonly observed in malignant mesothelioma and in metastatic cancer** (see Chap. 26). **Further, the nuclei of the mesothelial cells in such clusters may contain visible**, although not necessarily large, **nucleoli** (Fig. 25-16). The presence of marked inflammation and necrosis in smear background and clinical history may prevent the erroneous diagnosis of cancer by an alert observer.

In general, the **specific diagnosis of tuberculosis cannot be made on the basis of fluid cytology, but can be suspected if granulomas are identified**. The **Langhans' type giant cells are not specific for tuberculosis** and may represent a variety of other inflammatory or reactive processes (see Fig. 25-11D). **Granulomas may be observed on pleural or**

peritoneal biopsies which should be a part of proper work-up of patients. While direct microbiologic studies of fluids are usually of limited yield (Storey et al, 1976), the diagnosis must be confirmed by culture.

Syphilis

Zacharopoulos and Wong (1997) reported a rare case of syphilitic pneumonia and pleuritis in an HIV-1 positive, but not immunodeficient male patient. The disease was diagnosed on a skin biopsy showing granulomatous inflammation and confirmed by identification of **spirocheta pallida**, the causative agent. **Pleural fluid contained lymphocytes and macrophages**, some with foamy cytoplasm. The spirochetes could be identified in pleural fluid in the May-Grünwald-Giemsa and Steiner silver stains.

Identification of Specific Microorganisms in Effusions

Legionella micdadei

The causative agent of Legionnaires' disease can be identified in bronchial washings and pleural fluid. The organism is described in Chapter 19.

Figure 25-16 Ascitic fluid in a case of peritoneal tuberculosis. *A,B.* Proliferation of mesothelial cells, forming papillary clusters and mimicking metastatic carcinoma. *C.* Peritoneal biopsy containing granulomas. (Courtesy of Dr. Lucy Feiner.)

Pneumocystis carinii

The presence of this microorganism in pleural fluid in patients with AIDS was reported by several observers (Balachandran et al, 1990; Elwood et al, 1991; Abati et al, 1992; Delfs-Jegge et al, 1994). The organism was described in

P.934

detail in Chapter 19. In a personal case, we noted that **erythrocytes** in effusions may stain with Grocott silver stain and thus **mimic Pneumocystis**.

Fungi

Histoplasma capsulatum pericarditis was described by Kaplan and Sherwood (1963).

Cryptococcosis in a patient with AIDS was described by Katz et al (1989).

Viruses

Cytomegalovirus (CMV) inclusions were observed in pleural fluid in a patient with AIDS by Delfs-Jegge et al (1994). From time to time, we have observed **nuclear inclusions somewhat similar to CMV in cells in pleural fluids** but the exact nature of these inclusions has not been determined.

Parasites

The diagnosis of **congenital toxoplasmosis**, established in ascitic fluid, was reported by Nicol and Geisinger (1998). For description of trophozoites of the intracellular parasite, ***Toxoplasma gondii***, see Chapter 42.

Microfilariae of ***Mansonella ozzardi*** were observed in **ascitic fluid** by Figueroa (1973) (Fig. 25-17A). **Ova of the lung fluke *Paragonimus kellicotti*** were observed in a subcutaneous cyst fluid by McCallum (1975).

***Strongyloides stercoralis* larvae** (see Chap. 19) were observed in **ascitic fluid** by Avagnina et al (1980) in an immunosuppressed renal transplant patient. The authors postulated that the larvae penetrated the wall of the bowel in a patient in whom the infestation was confirmed at autopsy.

Giardia lamblia cysts and trophozoites (see Chap. 24) were observed in **peritoneal fluid** after a blunt trauma to the abdomen (Block et al, 1987).

Trichomonas vaginalis have been observed in pleural effusions (Memik, 1968) and were reported as a cause of an empyema (Miller et al, 1982).

Jacobson (1973) described a case of **echinococcosis** diagnosed in **pleural fluid**. In our own case, the characteristic **scolex and hooklets of *Echinococcus granulosus*** were readily observed (Fig. 25-17B). Other examples of echinococcosis are provided elsewhere in this book (see Chap. 19). It should be noted that the fluid of echinococcal cysts is highly antigenic and, if it is released from a cyst during aspiration, it may cause a severe anaphylactic reaction in the patient. Thus, no deliberate attempt at aspiration in a case of suspected echinococcosis should be made.

Figure 25-17 Parasites in effusions. A. Ascitic fluid containing filaria. B. Echinococcus. The hooklets of the scolex are well shown. (A: From Dr. Jesus Figueroa Giorgas Hospital, the Republic of Panama.)

Eosinophilic Pleural Effusion

This group of diseases is characterized by a **chronic but self-limiting pleural effusion, containing eosinophils**. There is lack of universal agreement about when an effusion should be so designated; the majority of authors suggest 10% of eosinophils as an acceptable criterion but others (Robertson, 1954) raise this to 50%. In my experience **10% eosinophils is sufficient to designate a fluid as belonging to this group of diseases with their uniquely favorable prognosis**.

Cytology and Pleural Biopsies

On **cytologic examination of the sediment**, the key feature is the presence of numerous bilobate eosinophils, accompanied by lymphocytes, scarce mesothelial cells, which may be quite atypical, macrophages, and occasional plasma cells (Fig. 25-18). **Pleural biopsies** show either fibrosis of the pleura or mild chronic inflammation with deposition of fibrin. **Eosinophils may be observed only in about 25% of all pleural biopsies**, suggesting that the eosinophils in the fluid may be derived from the peripheral blood. We and Naylor and Novak (1985) observed **Charcot-Leyden crystals** in several such cases (see Fig. 25-13A)

Etiology and Clinical Data

The exact etiology of this ill-defined group of diseases is not clearly understood. A number of factors, including allergy and hypersensitivity to drugs, trauma to the chest with resulting hemothorax (Contino and Vance, 1966), pneumothorax (Spriggs, 1979), and asbestosis (Adelman et al, 1984), have been implicated in the pathogenesis of eosinophilic pleural effusion. Yet, **in a substantial proportion of such cases, no evidence of a sensitizing factor or other**

P.935

disease state can be identified and the term **idiopathic eosinophilic pleural effusion** is suggested for such cases (Veress et al, 1979). Synchronous **eosinophilia in the peripheral blood is rare**; hence, the effusion presumably reflects a **local event confined to the pleura**. Kokkola and Valta (1974) studied 78 patients with pleural fluid containing 10% or more eosinophils. In 42 (54%) patients, the effusion was **idiopathic**, 16 patients had some form of ill-defined "**collagen disease**" not confirmed by clinical data, 6 had **cancer**, and 14 had **tuberculosis**.

Figure 25-18 Eosinophilic pleural effusion (idiopathic). *A.* Chest x-ray in a 34-year-old man with bilateral effusion causing severe dyspnea. *B.* Smear of pleural fluid showing isolated mesothelial cells, vacuolated macrophages, and numerous bilobed eosinophiles. *C.* Biopsy of pleura in the same patient showing minimal fibrosis. *D.* Pleural fluid from another patient, containing only eosinophiles.

Of particular interest is **idiopathic eosinophilic pleural effusion** (see Fig. 25-18). The disease is **usually unilateral, although bilateral effusion has been observed**. It is not infrequent to observe it in young, otherwise healthy people whose sole complaints are referable to a long-standing accumulation of pleural fluid. Occasionally, the disease may be totally disabling because of dyspnea. Veress et al (1979) reviewed the data on 30 patients with eosinophilic pleural effusion observed at Montefiore Hospital in New York City between May 1974 and January 1977. There were 11 patients younger than 50 and 19 patients older than 50, reflecting the hospital population. Six patients had a past history of cancer. Four patients had a history of asthma, 8 of thoracic trauma and, in 10 patients no other disease factors were observed. The summary of the key laboratory observations is given in Table 25-1.

It may be seen that **eosinophilia in pleural fluid was accompanied by lymphocytosis**. The fluids had a high specific gravity and high protein content, indicating that they were **exudates**. **Lactic dehydrogenase (LDH) activity was within normal limits**, in contrast with cancerous effusions (see Chap. 26). Eosinophilia in the pleural fluid did not correlate with findings in the peripheral blood. Only 4 of our 30 patients had blood eosinophilia of 10% or more.

Regardless of the etiology and pathogenesis of the eosinophilic pleural effusion, it is usually self-limiting and **has an excellent prognosis**, although its course may be protracted, sometimes lasting 2 years. Twenty-eight of the 30 Montefiore Hospital patients had adequate follow-up. Six patients died of myocardial infarction. In the remaining 22 patients, including the 6 patients with past history of cancer, **the effusion cleared up without specific treatment**. **Eosinophilic pleural effusion is a unique disease in which an accurate**

cytologic evaluation of pleural fluid offers an excellent prognosis for patients in alarming clinical situations.

TABLE 25-1 MONTEFIORE MEDICAL CENTER: SUMMARY OF SOME IMPORTANT LABORATORY DATA IN 30 PATIENTS WITH EOSINOPHILIC PLEURAL EFFUSION

	Blood		Pleural Effusion	
	Range	Mean	Range	Mean
Eosinophils (%)	0-50	7.17	12-85	38 (<i>n</i> = 43)*
Lymphocytes (%)	7-48	20.2	5-73	34 (<i>n</i> = 43)
Total protein g/dl	5.2-8.3	6.9	2-5.9	4.19 (<i>n</i> = 33)
LDH (IU)†	124-1240	331	71-600	267 (<i>n</i> = 32)
Specific gravity			1.016-1.037	1.027 (<i>n</i> = 16)

* *n*, number of patients.

† LDH (IU), lactic dehydrogenase in international units per liter.

Cirrhosis of Liver

Cirrhosis of liver, regardless of its etiology, results in a disturbance of the circulatory circuits in the abdominal cavity because of **fibrosis of portal spaces, affecting hepatic arteries and veins. Accumulation of ascitic fluid** is a common event in advanced cirrhosis. The cytologic investigation of **ascitic fluid**, particularly in patients with evidence of hepatic dysfunction, is often of crucial clinical diagnostic importance. The **clinical differential diagnosis of ascites**, comprising cirrhosis of the liver and various forms of primary

P.937

or metastatic cancer, may or may not be resolved on radiologic examination and a cytologic assessment may offer a rapid and cost-effective guidance as to the etiology of ascites.

Figure 25-19 Cell abnormalities in cirrhosis of the liver. *A-C.* Clusters and multinucleated cells in a somewhat overstained smear. The nuclear abnormalities mimic a malignant tumor. *D.* Histologic section of liver from the same patient obtained at postmortem examination showing cirrhosis and some evidence of regeneration. (*C*: high magnification.)

Cytology of Ascitic Fluids

In most patients, the ascitic fluid in cirrhosis of the liver does not present a diagnostic challenge. The fluids are **straw-colored exudates**. The **cell population** is sparse and easily identified as mesothelial cells or macrophages, and there is a minimal inflammatory component. In patients with ascites of long duration, **particularly after several previous taps, marked proliferation of mesothelial cells**, often accompanied by marked atypia, may occur (Fig. 25-19). **Cell-in-cell arrangement, suggestive of phagocytosis, papillary or rosette-like clusters of mesothelial cells** showing **nuclear enlargement, hyperchromasia, and slight irregularities of nuclear contour** may occur (Fig. 25-20). The atypical mesothelial cell nuclei are **generally of fairly monotonous, even size and do not have large nucleoli**. Such clusters may be accompanied by **multinucleated macrophages**, most likely the reaction to previous taps, which may suggest to an uninitiated observer giant cancer cells.

Cell abnormalities may be particularly troubling in the rare jaundiced cirrhotic patients with massive liver failure. The ascitic fluid in such patients may contain large, bizarre cells, sometimes with prominent nucleoli that may be of hepatic, rather than mesothelial derivation.

Figure 25-20 Another example of mesothelial cell atypia in cirrhosis of the liver. *A*. A cluster of mesothelial cells with somewhat enlarged nuclei. *B-D*. Examples of cell-in-cell arrangement of mesothelial cells, incorporated either by macrophages or other mesothelial cells, a finding commonly observed in ascites in advanced cirrhosis.

The **distinction between the markedly atypical mesothelial cells and cancer cells in such situations is difficult**, particularly in patients with liver failure. The **absence of prominent nucleoli** in the atypical mesothelial cells and the **presence of multinucleated macrophages** are important cytologic clues that the lesion is benign. It should be noted that the **association of cirrhosis of the liver with metastatic cancer is uncommon**. The only malignant tumor consistently associated with cirrhosis is **hepatocellular carcinoma** and these tumors very rarely shed cells into the ascitic fluid, although such events have been noted (see Chap. 26). **In patients with cirrhosis, the diagnosis of cancer in ascitic fluid should not be made in the absence of supportive clinical history and computed tomography.**

It is of interest here that To et al (1981) and Watts et al (1983) observed **major chromosomal abnormalities in cultures and direct spreads of mesothelial cells from ascitic fluid of five patients with alcoholic cirrhosis of the liver**. Metaphase spreads with over 70 chromosomes, clones of abnormal cells with marker chromosomes, and other major cytogenetic abnormalities were reported. **The authors suggested that these startling findings represented**

P.938

an alcohol-induced transformation of mesothelial cells. A confirmation of this apparently unique observation would be desirable because, in practice, mitotic abnormalities in effusions are extremely rare in the absence of cancer. The possibility that the highly abnormal cells, as are shown in Figures 25-19 and 25-20, are transformed mesothelial cells with an abnormal chromosomal component, cannot be ruled out.

Pancreatitis

Effusions associated with acute or chronic pancreatitis are usually limited to the abdominal cavity. **Ascitic fluid** that may be observed in pancreatitis is very rarely aspirated after the

clinical diagnosis has been established. Kutty et al (1981) pointed out that **pleural fluid accumulations, that may be sometimes observed in pancreatitis, may contain abnormal mesothelial cells mimicking a malignant tumor.** The changes described and illustrated were very similar to those shown below in uremia (Fig. 25-21).

Renal Diseases

It is uncommon to associate renal diseases with cytology of effusions. Such links, however, do exist as, for example, in **hypoproteinemia** (see above), uremia, and dialysis ascites.

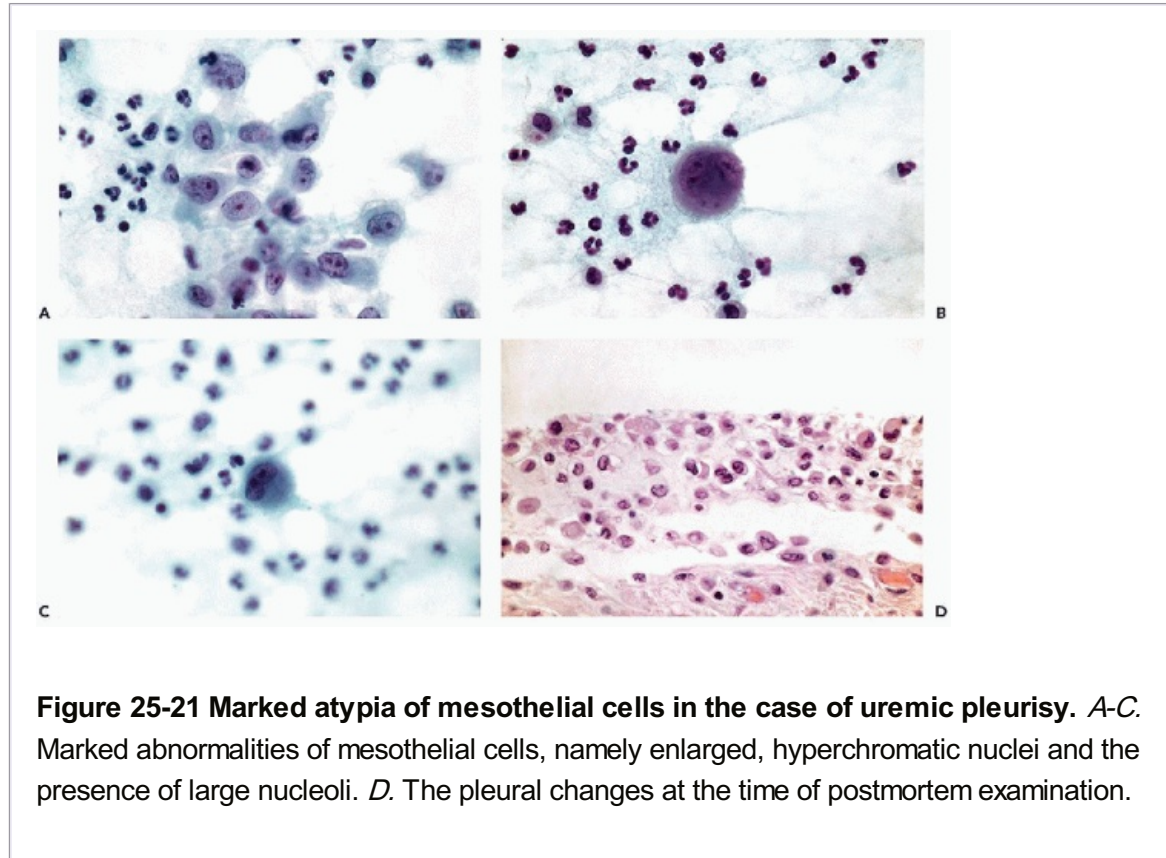

Figure 25-21 Marked atypia of mesothelial cells in the case of uremic pleurisy. A-C. Marked abnormalities of mesothelial cells, namely enlarged, hyperchromatic nuclei and the presence of large nucleoli. **D.** The pleural changes at the time of postmortem examination.

Uremia

Uremic pericarditis has long been recognized as a frequent and ominous feature of uremia. The cytology of uremic pericarditis is unknown because the fluid is virtually never aspirated. On occasion, **uremic pleurisy** may develop, and the pleural fluid may contain **numerous atypical mesothelial cells**. In exceptional cases, such as the one illustrated in Figure 25-21, **highly abnormal mono- and multinucleated mesothelial cells, occasionally with markedly enlarged nuclei and multiple, irregularly shaped nucleoli, may be observed. In this case, these cells were unequivocally classified as malignant,** but a careful postmortem examination revealed only an abnormal proliferation of the mesothelium. Although this case seems exceptional, **occasional mistakes due to abnormal proliferation of mesothelial cells in uremia seem unavoidable.**

Dialysis Ascites

Some patients receiving peritoneal dialysis or hemodialysis develop a nearly intractable **chronic accumulation of ascitic fluid.** The ascites disappears after surgical removal of the kidneys. In seven cases of dialysis ascites personally studied, the only cytologic observation of

note was the presence of **erythrophagocytosis** (Fig. 25-22A). It is not known by what mechanism the red blood cells become sensitized and ingested; nor is it known whether the cells containing ingested erythrocytes are mesothelial or macrophages. Biopsies

P.939

of peritoneum in dialysis ascites disclose fibrinous peritonitis, with a slight to moderate proliferation of mesothelial cells (Fig. 25-22B). Yanez-Mó et al (2003) reported that, in the course of peritoneal dialysis, the mesothelial cells may assume the properties of fibroblasts.

Figure 25-22 Dialysis ascites. A. Erythrophagocytosis in a case of dialysis ascites. The peritoneal biopsy in this same case shows some fibrosis and proliferation of mesothelial cells.

Collagen Diseases

Pleural effusions, and occasionally ascites, are not rare in the ill-defined group of diseases that have in common degenerative or inflammatory changes in tissues derived from the embryonal mesenchyme. Necrosis of small blood vessels and inflammatory perivascular changes are some of the common morphologic denominators of this group of disorders that otherwise have diverse clinical manifestations.

Figure 25-23 Pleural fluid in lupus erythematosus. A-C. LE cells showing phagocytosis of lymphocytes with pyknotic, homogeneous, degenerated nuclei. D. The so-called Tart, cells somewhat similar to LE cells but without pyknosis of the phagocytized lymphocytes. (A-D: H&E; A: oil immersion; B-D: high magnification; D: Courtesy of Dr. Bernard Naylor, Ann Arbor, MI.)

Systemic (Disseminated) Lupus Erythematosus

Clinical Data

Systemic lupus erythematosus is an auto-immune disorder, usually affecting multiple organs of young women, but

P.940

also observed in children, older female and male patients (Scully et al, 2001, Case Record 19-2001, Massachusetts General Hospital). The disease is characterized by generalized malaise and fever, arthritis affecting multiple joints, skin manifestations ("butterfly" erythema of face) and renal involvement. **Pleural effusions** are a common manifestation in this disorder and the cytologic examination of the sediment may be the first objective evidence of this disease.

The sera of these patients contain anti-nuclear (anti-DNA) antibodies that destroy the DNA of cells. The dead cells (mainly leukocytes) are phagocytized by other leukocytes or by macrophages, forming the characteristic lupus erythematosus (LE) cell.

Cytology

The finding of a **degenerated, homogeneous nucleus of a leukocyte phagocytized by another leukocyte, the so-called lupus erythematosus (LE) cell, is, with few exceptions, pathognomonic of this disease.** The exceptions are **drug-induced disorders**, mainly procainamide hydrochloride (Kaplan et al, 1978), **and occasional patients with effusion but no evidence of either lupus or drug intake.** The LE cells may be produced in vitro by incubating patient's blood at 37°C. It is, therefore, not surprising that in effusions, which offer optimal conditions for incubation, LE cells will be observed, usually accompanied by an inflammatory reaction (Fig. 25-23A-C).

Figure 25-24 Pleural fluid in rheumatoid arthritis in a 34-year-old woman. *A.* Spindly cells in a background of necrotic material. *B.* High-power view of multinucleated spindly cells in a background of homogeneous necrotic material. *C.* Papillary clusters of mesothelial cells surrounded by necrotic material. *D.* Pleural biopsy in the same patient showing typical rheumatoid nodule of the pleura. (Case courtesy of Dr. Bernard Naylor, Ann Arbor, MI.)

The LE cells have been observed in **pleural, ascitic, and synovial fluids of patients with lupus erythematosus** (Pandya, 1976; Metzger et al, 1974; Hunder and Pierre, 1970; Reda and Baigelman, 1980; Good et al, 1983; Naylor, 1992; Scully et al, 1999; Case Record 14-1999, Massachusetts General Hospital). Fazio et al (1998) described a case of **cardiac tamponade** with LE cells in the pericardial fluid.

Besides LE cells, other cytologic abnormalities may be observed. Thus, Kelley et al (1971) described **large atypical cells, akin to plasma cells**, in pleural fluids in eight of ten patients with systemic lupus. These authors considered these cells of great significance for early diagnosis of this disease. Naylor (1992) reported on the presence of “**tart cells**,” or small macrophages, that have phagocytized nonhomogenized but degenerated nuclei, presumably of lymphocytes, first described by Hargraves et al in 1948 (Fig. 25-23D).

The pleural effusions in patients with lupus have high protein content (over 3 g/100 ml) and glucose content of more than 55 mg/100 ml. This latter value is in **contradistinction to rheumatoid arthritis** wherein pleural effusions usually have glucose levels of less than 20 mg/100 ml of

P.941

fluid. Good et al (1983) noted that the level of **anti-nuclear antibodies**, a hallmark of lupus erythematosus, is often very high in pleural fluids of these patients.

Rheumatoid Arthritis

Clinical Data

Rheumatoid arthritis is a **chronic autoimmune disease** mainly affecting synovial membranes

of joints, and characterized by formation of **granulomatous nodules composed of a necrotic core and peripheral epithelioid cells, arranged in a palisade**. Such nodules may be observed in a variety of organs, including lung, pleura, pericardium, and heart (Yurchak and Deshpande, 2003, Case Record 2-2003, Massachusetts General Hospital).

Cytology

In 1968, Nosanchuk and Naylor described a characteristic cytologic picture in **pleural effusions** in five of ten patients with rheumatoid arthritis. The principal feature is the **background, made up of granular, amorphous, particulate acellular debris of various hues**. The material is sometimes eosinophilic, sometimes more cyanophilic, or even green, in Papanicolaou stain. Within this background there are **elongated, fibroblast-like cells (epithelioid cells) and numerous multinucleated, often elongated, giant cells and degenerating leukocytes**. The **combination of the debris, spindle cells, and multinucleated giant cells in fluids is pathognomonic for rheumatoid arthritis** (Figs. 25-24 and 25-25). The origin of these cells is from the **rheumatoid nodules** involving the pleural cavity. The granular material originates in the necrotic part of the nodule (Figs. 25-24D and 25-25D). The spindle and giant cells originate in the characteristic "palisading" epithelioid cell lining the periphery of rheumatoid nodules. Boddington et al (1971) pointed out that the presence of the **amorphous material alone is also diagnostic**

P.942

of rheumatoid effusion. They further reported that the amorphous material fluoresced with anti-gamma globulin antisera, a reaction that was not observed in control fluids. Naylor (1990B) also observed **cholesterol crystals** in pleural effusions of several patients.

Figure 25-25 Pleural fluid in rheumatoid arthritis in a 75-year-old man. *A.* Chest x-ray of patient showing marked left pleural effusion. *B,C.* Various forms of atypical spindly and multinucleated cells within the background of homogeneous necrotic material. *D.* Biopsy of pleura showing a rheumatoid nodule.

Ragocytes, or RE cells, first described in synovial fluid of patients with rheumatoid arthritis, are neutrophilic polymorphonuclear leukocytes with cytoplasmic inclusions resembling seeds of grapes (from Greek, *rago* = grape). For further description of these cells, see Chapter 27. Naylor (1990B) observed such cells in effusions in rheumatoid pleurisy, but did **not** consider them to be of diagnostic value.

Figure 25-26 A-C. Highly abnormal mesothelial cells in chylous ascites of long standing, associated with diffuse scleroderma. The markedly enlarged, hyperchromatic nuclei strongly suggest malignant cells. D. Skin showing changes of scleroderma. E. High-power view of the serosal lining of the small bowel in the same case at autopsy. The origin of the abnormal cells in the serosa is clearly demonstrated.

Boddington et al (1971) pointed out that effusions associated with rheumatoid arthritis **occur more often in males than statistically warranted and that they may occur at any time during the course of the primary disease and even as the first manifestation of rheumatoid arthritis**. We can confirm these observations, as did Naylor (1990B). It is of note that glucose content of fluids showing this cytologic picture is generally below 20 mg/100 ml (Carr et al, 1970; Carr, 1973).

Patients with rheumatoid arthritis without rheumatoid granulomas in the pleura may also develop pleural effusion that does not show the characteristic cytologic picture.

P.943

Scleroderma (Progressive Systemic Sclerosis)

For comments on the nature of this disease, see Chapter 24. We have observed a male patient with this disorder with **chylous ascites**, apparently caused by obstruction of thoracic duct. The

sediment of the ascitic fluid contained mesothelial **cells with markedly hyperchromatic, enlarged nuclei** (Fig. 25-26). At autopsy, the origin of the cells could be traced to abnormal peritoneal lining.

Langerhans' Cell Histiocytosis

This uncommon disorder with many manifestations, discussed in Chapter 19, may be associated with effusions, as reported by Nagaoka et al (1996). The characteristic Langerhans' cells resemble macrophages, have scanty cytoplasm with long processes, and **large, cleaved nuclei**, and are often accompanied by eosinophiles. A positive immunostain for protein S-100 and antibody CD1 confirms the identity of these cells. The effusions may be associated with pulmonary disease which sometimes produces pneumothorax and even broncho-pulmonary fistulae.

Figure 25-27 Effect of treatment on cells in effusions. *A.* Radioactive phosphorous (P^{32}). Note marked vacuole formation in the cytoplasm of cancer cells. *B.* Radiotherapy. Markedly atypical, but benign, mesothelial cells from pleural fluid of a 30-year-old woman with mediastinal Hodgkin's disease treated by radiotherapy. The cells form an acinar structure and prominent nucleoli, mimicking cancer. *C, D.* Radiotherapy. Pleural fluid 6 years after completion of radiotherapy for ipsilateral breast cancer. *C.* The mesothelial cells, singly and in clusters, show enlarged, somewhat hyperchromatic nuclei. Smear background contains lymphocytes. *D.* Mesothelial cells form surface blebs (High magnification).

Miscellaneous Cytologic Abnormalities

Effects of Radiotherapy

Patients treated for cancer may develop effusions that are either caused by recurrent or metastatic tumor or may be unrelated to primary disease and caused by inflammatory events or by effects of therapy. The effects of **chemotherapy** may be sometimes evaluated in cancerous

effusions, as discussed in Chapter 26. More commonly, however, **radiotherapy**, either administered to a target enclosed by a serous cavity or adjacent to it, may be associated with synchronous or metachronous effusions. The cytologic evaluation of such effusions represents sometimes a diagnostic challenge because radiotherapy-induced abnormalities of mesothelial cells may be mistaken for cancer.

Radioactive Phosphorous (P^{32})

Treatment of chronic pleural effusions, by radioactive phosphorous, is rarely used today, even in patients with cancer. There is no systematic study of the effects of P^{32} on benign cells, although anecdotal experience suggests that **marked enlargement, vacuolization of the cytoplasm and of the**

P.944

nuclei of mesothelial cells and macrophages occurred in treated patients (Fig. 25-27A).

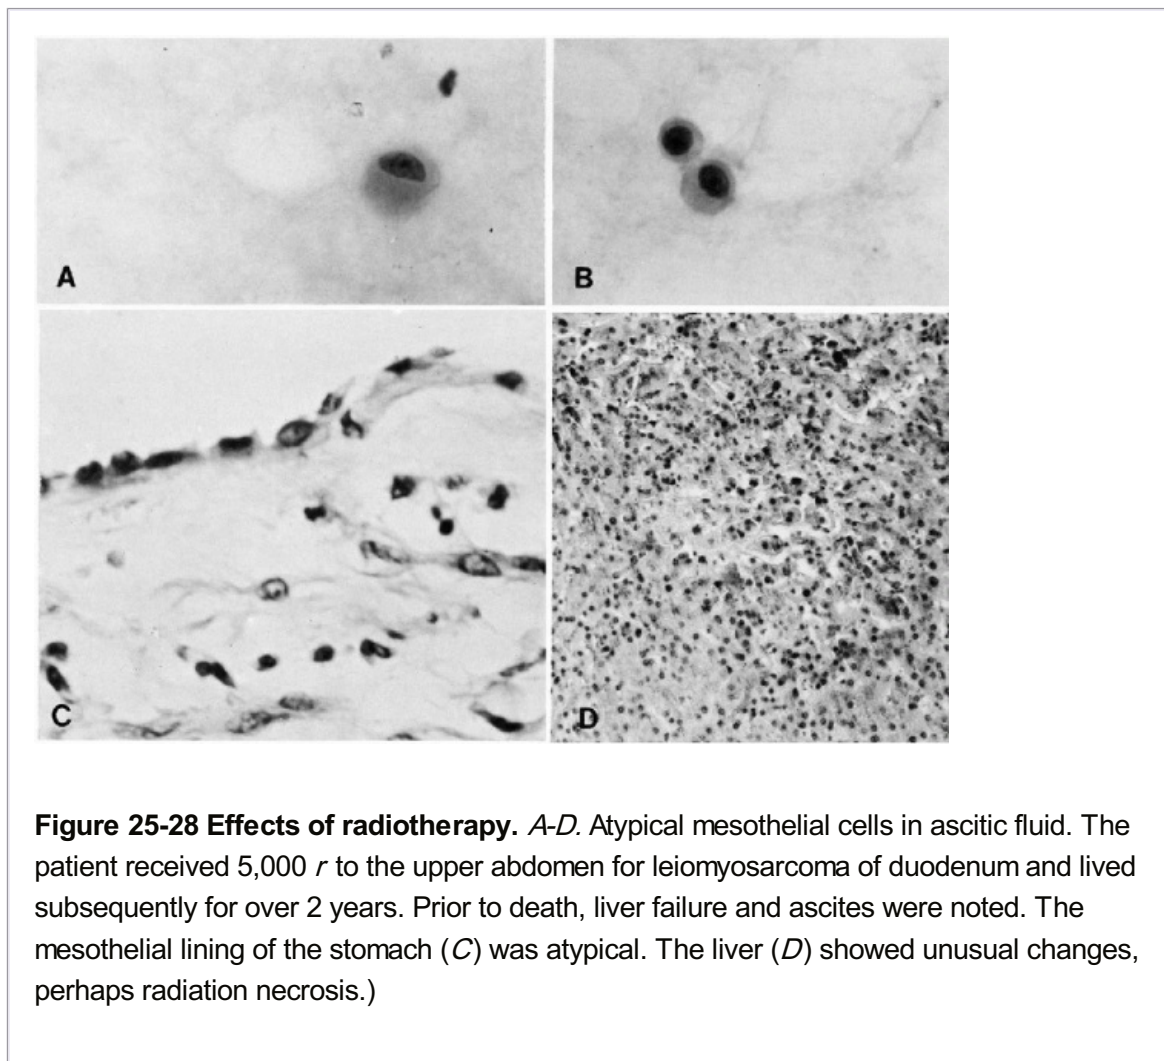

Figure 25-28 Effects of radiotherapy. A-D. Atypical mesothelial cells in ascitic fluid. The patient received 5,000 r to the upper abdomen for leiomyosarcoma of duodenum and lived subsequently for over 2 years. Prior to death, liver failure and ascites were noted. The mesothelial lining of the stomach (C) was atypical. The liver (D) showed unusual changes, perhaps radiation necrosis.)

External Radiotherapy

Wojno et al (1994) compared the results of external radiotherapy in 55 pleural fluids from treated patients with 39 control specimens from untreated patients with cancer. These authors evaluated a large number of features of benign mesothelial cells in both groups of patients and concluded that there are no specific mesothelial abnormalities attributable to radiotherapy, regardless of the amount of radiation and time interval since conclusion of treatment. Only

“bizarre mesothelial cells” (not further defined) were somewhat more frequent in irradiated patients than in controls. Other cell features, such as “degenerative changes” (not further defined), smudgy chromatin, large cytoplasmic vacuoles and cytomegaly were somewhat more common in the fluids of irradiated patients but failed to reach statistical significance. The paper did not state whether these patients received other forms of therapy.

In spite of this pessimistic assessment, there is again anecdotal evidence that external radiotherapy may cause abnormalities of mesothelial cells that may be observed in patients whose fluids do not contain cancer cells. In most such cases, the mesothelial cells retain their basic morphologic features but may be arranged in large spherical clusters and show prominent nucleoli (Fig. 25-27B). In yet other cases, the nuclei may show hyperchromasia (Fig. 25-27C) or formation of surface protrusions or “blebs” (Fig. 25-27D). As an example, **abnormally shaped mesothelial cells with considerable nuclear hyperchromasia** were observed in ascitic fluid in a patient who received 5,000 rad (50 Gy) to the abdomen for an inoperable leiomyosarcoma of the duodenum (Fig. 25-28). Two years after treatment, the patient died with jaundice and a considerable ascites. At autopsy, no tumor was found, but the peritoneal lining was histologically abnormal, while the liver displayed unusual necrotic changes, possibly a late result of radiation.

Amyloidosis

In a most unusual case of a patient with generalized amyloidosis and ascites of long duration (seen courtesy of Drs. David Jones and Eleanor Bechtold of Syracuse, NY), there were **clusters of mesothelial cells that had a strikingly abnormal pattern of nuclear chromatin with prominent nucleoli**, mimicking a malignant tumor (Fig. 25-29). There was no evidence of cancer in this patient.

Endometriosis

Endometriosis may cause an accumulation of bloody ascitic and sometimes pleural or even pericardial fluids that may be clinically alarming (Yu and Grimes, 1991; London and Parmley, 1993). A case of **endometriosis of the lung**

P.945

and pleura, diagnosed by aspiration biopsy (FNA) was recorded by Granberg and Willems (1977). Subsequently, Zaatari et al (1982) reported on two cases of **pleural endometriosis** with characteristic recurrent hemorrhagic effusion. **Endometrial cells of columnar configuration, singly and in clusters**, derived from the lining of the endometrial cyst, were described as characteristic of the disease process. The fluids also contained **hemosiderinladen macrophages** and clusters of smaller epithelial cells showing intercellular molding. Somewhat similar findings were reported by Kumar and Esfahani (1988) in **ascitic fluid in two patients with ruptured endometriotic ovarian cysts**. Besides the columnar epithelial cells described by Zaatari et al, **clusters of typical endometrial and small, spindly stromal cells** were observed. The endometrial epithelial cells formed flat sheets and glands, similar to those observed in direct endometrial samples (see Chap. 13). The Kumar and Esfahani observations were of significant diagnostic value because both their **patients were initially thought to have ruptured malignant tumors of ovary**. Similar observations were reported by Schlueter and McClennan (1994). In several recent case reports of blood fluids associated with endometriosis, **hemosiderincontaining macrophages** were the dominant cytologic findings (Dias et al, 2000; Francis et al, 2003). Cytologic findings in endometriosis are also described and illustrated in Chapters 22, 27, and 34.

Figure 25-29 A,B. Ascitic fluid of long standing in a case of diffuse amyloidosis proved by autopsy. Note the clustering of cells and striking hyperchromasia of nuclei of individual mesothelial cells. (Courtesy of Drs. David Jones and Eleanor Bechtold, Syracuse, NY.)

“Yellow Nail” Syndrome

“Yellow nail” syndrome is a rare, apparently reversible disorder characterized by **yellow color, slow growth, and absence of cuticles in fingers and toenails**. The syndrome, first described by Sammon and White (1964), is often associated with lymphedema and **pleural effusion** (Dilley et al, 1968; Dwek and Greenberg, 1973). It may be occasionally associated with cancer (Guin and Elleman, 1979) and a broad variety of other disorders, such as thyroid disease, rheumatoid arthritis, and immune deficiencies (review in DeCoste et al, 1990).

Information on the cytologic make-up of the effusions in this disease is very limited. In a case brought to my attention by Dr. Allan Olschewski, the **pleural fluid contained a rich population of active, atypical lymphocytes, lymphoblasts, and eosinophiles**. Pleural biopsies disclosed lymphocytic infiltration of the submesothelial connective tissue. The presence of atypical lymphocytes in the fluid led to a work-up of the patient for a malignant lymphoma with negative results.

SPECIAL FEATURES OF PERICARDIAL FLUID

The aspiration of pericardial fluid is not as simple a procedure as aspiration of the pleural or ascitic fluid. Because of the danger of myocardial perforation, the procedure is not undertaken lightly and only in patients in whom the diagnosis of pericardial effusion is a major dilemma or patients threatened with cardiac tamponade for whom a pericardial “window” must be established. The **differential diagnosis often comprises a primary tumor, such as a mesothelioma or involvement by a mediastinal tumor** (lymphoma, thymoma, seminoma, or malignant teratoma; see Chap. 37), a **metastatic tumor**, or a **chronic inflammatory process**, such as a rheumatic pericarditis or postinfarction pericarditis. All of the benign disorders cause atypias of mesothelial cells which deserve a special note.

Cytologic Findings in the Absence of Cancer

In my experience, the cytologic findings in benign pericardial fluids present an important diagnostic challenge. The **benign mesothelial cells in pericardial fluids may form large sheets with a spherical, hence, “papillary” configuration** (see Fig. 25-9C). Furthermore, it

is not uncommon to see rather **prominent nucleoli** in such cells. These findings may **mimic a malignant tumor**. The reasons for the high frequency of these findings is unclear and is probably

P.946

related to some special features of pericardial mesothelium about which nothing is known. Another source of diagnostic error may be **chronic hemorrhagic pericarditis**, with accumulation of **massive amounts of hemosiderin in macrophages, mimicking a malignant melanoma**. A positive iron stain may clarify the nature of the accumulated pigment.

Major diagnostic difficulties may occur in **chronic fibrosing pericarditis** that may lead to cardiac tamponade. In such pericardial fluids, one may observe large clusters of atypical mesothelial cells, occasional mitotic figure, and sheets of highly abnormal fibroblasts from areas of **granulation tissue**. Because the **actively proliferating fibroblasts** may show **significant nuclear abnormalities** in the form of prominent nucleoli and large hyperchromatic and atypical nuclei, such findings can be readily confused with a malignant tumor.

Other rare nonmalignant disorders causing pericardial effusions with marked proliferation of mesothelial cells include *Histoplasma capsulatum* pericarditis (Kaplan and Sherwood, 1963) and **tuberculous pericarditis** (Kapoor et al, 1973). For description of cytologic findings in tuberculosis, see above. **The cytologic diagnosis of cancer in pericardial fluids should be limited to cases with secure evidence of a malignant tumor.**
